The elastic element in the corium is very much reduced in amount everywhere. It is deficient in amount in the papillary and subpapillary zones, while in the neoplastic lobules elastin is represented solely by a few somewhat large and peculiarly straight rods.

CASE 5. *Syphilis.* Male aged forty-nine, machinist. Probably initial lesion three to four years ago. To-day has two exceedingly deep ulcers near scapula and near spinal column, accompanied by "rheumatic" pains. In three weeks the ulcers were entirely healed under iodide of potash and mercurial inunctions.

CASE 11. *Lupus Erythematosus?* Female aged thirty-seven, housework.

Has had chills once or twice weekly for four months up to two weeks before admittance to the hospital. Has not felt well or strong for four or five years. Several years ago had glands removed from the neck.

In February, 1910, patient thinks she froze her ears and nose. Two weeks later the present disease began in dry and grayish scales on the convalescent areas. In May pigmentation of the face appeared after sitting in the sun, and her family physician told her she had erysipelas.

On entrance one found dark red to brownish, or even purple, elevated areas covering the entire face and forehead and ears, and here and there one noted closely adherent, dirty, gray scales. Edema was present below each eye. The back of the hands and the arms presented red, dry, scaling, slightly elevated patches, pea to coin-sized. The fingers itched. Von Pirquet reaction negative, as was our examination of the nasal discharge for lepra bacilli.

The case was a diagnostic puzzle and to-day (Dec. 16, 1910) the woman lies in the ward again as a re-entrant. We may have here a paralyzed vascular network following the severe exposure of the affected parts to the winter's cold.

CASE 16. *Scrofuloderma.* Female aged fifteen, school.

Three years ago pain and stiffness and loss of strength developed in the child's wrist two weeks after vaccination. Hand and forearm were put up in plaster and when the dressing was removed two to three months later a discharging ulcer made its appearance and lasted for a year. Shortly after, other ulcers developed and have persisted ever since. On entrance, both forearms and wrists were undeveloped and the skin showed many foul, sluggish, deep ulcers with interspersed scars, and the right elbow and wrist were anchylosed at an angle of 45°. A radiograph indicated an accompanying osseous change. Physical examination was negative, Von Pirquet positive. No temperature.

These ulcers yielded slowly to Scharlach R dressing, but thorough curettage was performed later and great masses of necrotic tissue, extending down to the tendon sheaths were scooped out.

Case 19. *Herpes zoster.* Male aged sixty-two.

Right scapula, thoracic, axillary and brachial regions affected. Severe neuralgic pain, especially at night, which yielded very satisfactorily to freezing with ethyl chloride over the seats of origin in the spinal cord.

Case 20. *Syphilis.* Female aged twenty-four, jeweller.

Date of infection unknown. Present condition consisted of numerous ulcers of five months' duration on both lower legs. On right leg there were twelve, and on left two, and they ranged in size up to that of a silver half-dollar. A small brown cicatrix was found in left pubic region and a mucous plaque was present on the left side of the tongue. During the woman's visit three teeth were removed because of necrosis of left lower jaw. Patient was discouraged and hysterical. Thirty-three days after entrance all active lesions were healed.

Case 23. *Pemphigus foliaceus.* Female aged seventy-three.

For the last year has had frequent dizziness and headache and swelling of face. The cutaneous eruption developed about six months ago as yellowish "spots" on tongue, lips and buccal mucous membrane. These "spots" soon became blisters, and these blisters gave way to large exfoliated flakes. The disease then manifested itself on the chin in the form of blisters accompanied by a burning sensation.

On entrance the chin was free from eruption, but the oral cavity was still affected. The tongue was completely denuded and bore deep cracks. Scattered over the arms, axillæ, groins, trunk, buttocks, legs and feet were numbers of ruptured blebs with ragged epithelial coverings, or with completely denuded surface, or with sanguinolent moist crust. The patient was very weak, emaciated and poorly nourished and complained of intermittent itching.

During the remainder of her life a few new bullæ appeared, always flaccid, never tense. The great heat was very depressing to the patient, her appetite was never good; nausea developed and disappeared; delirium was present. Later a great change took place. Old lesions had healed and but few new ones had developed, and the prognosis looked favorable. Five weeks after entrance, however, flaccid bullæ appeared, delirium returned, the appetite failed and the final decline commenced, death occurring fifty-nine days after entrance, nine or ten months after the original outbreak. No autopsy was permitted.

Case 32. *Prurigo.* Female aged thirteen, school.

This young girl had been in our ward on three or four previous occasions. A few days of hospital life, with its healthy conditions of air, food, sleep and medical care, had always brought about a rapid amelioration of her skin lesions and she was always discharged practically free from visible signs of disease after a few weeks' sojourn in the ward. Despite her apparent cure, the child would always return to the out-patient clinic a week or more later with the disease as evident as ever. This had been our previous experience, and we were destined to see the cycle repeated once again.

On entrance the eruption was a perfect replica of previous attacks. The cheeks and forehead were very flushed and studded thickly with firm, hard, shotty papules. The arms and legs were similarly affected, but the lower legs and the lower arms were much more abundantly broken out and the extensor surfaces of both arms and legs were more affected than the flexors. Palpable glands were numerous and widely scattered.

This was a typical example of prurigo mitis, and hospital hygiene, soothing washes, carbohydrate diet and intestinal antiseptics brought about their usual rapid favorable results, and nineteen days after entrance the girl was discharged nearly free from outward manifestations of her disease. To-day, Feb. 20, the disease has apparently wholly disappeared.

Case 34. *Trophic ulcer.* Female aged thirty-six, dressmaker.

This patient had a long surgical and dermatological history and had been in the hospital numerous times. Her adolescence was interrupted by numerous illnesses, including measles, scarlatina, diphtheria, mumps, multiple cervical abscesses, etc. On top of this history was the story of the death of five brothers and sisters in childhood, three of which were due to phthisis. The long, persistent affection of the foot dated back twenty-four years. It began like chilblains (lupus pernio?), followed by atrophy and ulceration and total destruction of toes, until all had fallen off progressively from the big toe outward. The present trouble consisted of an ulcer on the dorsum of the foot, accompanied by great pain, but controllable by hot water. The ulcer responded well to treatment and was nearly healed in sixteen days.

Case 36. *Dermatitis herpetiformis.* Female aged five.

For the last four summers the patient has had a similar outbreak, but never so extensively as at present. Four months before entrance the child had scarlatina, and one month later the present outbreak began. The general physical examination revealed no abnormalities apart from the skin lesions, which consisted of small and large herpetiform vesicles scattered over the entire body and extremities. Many lesions had coalesced and crusted, and between them appeared numerous pigmented macules, the remains of previous outbreaks. The blood showed 13% of eosinophiles; indican was usually deficient in amount. Two weeks after entrance the production of new vesicles had ceased, and the patient's skin was free from active lesions. This, however, was merely a quiescent period of the disease, perhaps induced by Fowler's solution (M. v, t. i. d.) and by the external application of 50% ichthyol. During the rest of the child's stay in the ward (five weeks) there were always a few grouped vesico-bullæ present, usually on the wrists and dorsum of feet.

Case 43. *Xeroderma pigmentosum.* Female, Irish, aged eleven, school.

Brothers and sisters living and well. This is the first example of this rare disease observed in this hospital in only one member of the family, and also the first case outside of the Russian Jews. At the age of three months in the month of February this child was taken out of doors for the first time. The following day the mother noticed a considerable erythema of the face followed at once by freckling which had persisted, receding every winter and reappearing more

intensely every summer. At seven years of age the eyes became "sore" and were examined and glasses were prescribed. One year ago a growth developed on the right eye which has persisted and the visiting ophthalmologist records: "Pseudo-pterygium of right eye, scars on the left cornea, and chronic conjunctivitis and blepharitis of both eyes." The present dermatosis was limited to the entire face, ears, neck, hands and forearms, most markedly on the face, where there were many pinhead to small pea-sized, reddish-brown to chocolate-brown macules associated with a few punctiform or linear telangiectases. The interlying skin was atrophic, thin and wrinkled, and in places desquamating. On the left ala of the nose there were several keratoses; while on the right cheek a well-developed but small epithelioma was present. The child as a whole was undersized and the face looked pinched and old. The child was kept in a darkened room by day and spent the evenings and nights out of doors. The keratoses and epithelioma were curetted and excised, and after a sojourn of six weeks in the ward the child, much improved in appearance, was transferred to the Eye and Ear Infirmary.

HISTOLOGY.

The epidermis is very abnormal for the most part. In its most typical areas the layer as a whole is thin and the boundary between corium and palisade layer is indefinite and difficult to define — a precancerous state. Above this malformed basal layer there are only a few strata of spinous cells, and these cells, even, are abnormal; some have large perinuclear halos, others are entirely wanting. Above these atypical layers the granular cells are absent and, surmounting all, we find parakeratosis.

*Corium.* — As a whole this portion of the skin can best be described as fragmentary. Below the most diseased areas there are collections of lymphocytes seeming to connect with the broken epidermic line by a pedicle and spreading out below into a rounded mass of lymphocytes. In places the sebaceous glands seem irregular in their make-up. Vessels are not conspicuous and elastin resembles connective tissue in its disjointed look.

EPITHELIOMA ON XERODERMA PIGMENTOSUM.

The epidermis of the non-ulcerated portion is very hyperplastic. The rete consists of many layers of cells, and as one approaches the epitheliomatous area the boundry between epidermis and corium becomes ill-defined, and epithelial down-shoots appear. In the ulcerating epitheliomatous area, cellular confusion is conspicuous. Here one sees all manner of degeneration — cavitary and ballooning especially. Scattered through this area are whorls and irregular masses of epithelial cells mixed up with great outpouring of inflammatory cells. These epithelial masses show cells of great size with central rarefaction. Widely dilated sweat glands occupy a conspicuous place in the picture, appearing very high up in the sections. In addition, there are many dilated capillaries and hypertrophied veins. The corium as a whole is markedly disrupted by cellular invasions, principally lymphocytic. As one would infer from the foregoing description, elastin is conspicuous by its absence. On the whole, the histological picture is a remarkable one.

CASE 46. *Scrofuloderma.* Male aged eleven.

Multiple crusting ulcers in a negro boy about eyes, jaw, neck and clavicles. Dullness in left lung; ankylosis of left elbow; evening temperature of 99.

CASE 47. *Dysidrosis.* Female aged eleven, school. Bullæ of both feet, especially of plantar surfaces, and, to a lesser extent, of all fingers on their lateral surfaces. There was in addition a marked hyperidrosis present. These active lesions dated back only two weeks, but the patient had suffered much for the past six or seven years from itching of the feet.

CASE 50. *Purpura.* Female aged three.

Family history negative. The extensive hemorrhages into the skin of face, scalp, tongue, chest, arms and shoulders developed suddenly four days previously without discernible cause and without other objective physical symptoms.

CASE 51. *Dermatitis exfoliativa.* Male aged twenty-four, clerk.

A sore developed on the penis about March 1, became phagedenic but was healed in about six weeks. One week later a faint roseola appeared and the man began to take internally some capsules and to rub in externally "mercurettes." This was done for more than six weeks. In June a week of malaise, sore throat, etc. In late July noticed vesicles on lateral aspects of fingers, and one week later "water blisters" between scapulæ and on face. On Aug. 26 the patient entered the hospital in a state of universal desquamation. The scales were large, thick, loose at periphery and attached at the center. There was considerable moisture about the face and there were remains of bullæ about the ankles. Itching was a marked feature and the skin as a whole was of a dusky red hue. The general physical condition was good, insomnia and pruritus being the only marked pathological features. Twelve days later the mental condition became clouded and the man was restless and irritable, but in another week the skin began to be less moist and to desquamate less and the patient became more normal mentally. So it went with ups and downs until the middle of October, when the skin was nearly normal in color and quite dry, and the desquamated scales were much smaller in size than at any previous time. A few days later, however, the sacral skin became moist and erythematous, then the same conditions developed on the legs and finally the whole body surface became moist, dusky red and rather denuded of scales. Improvement again followed but the patient became tired of his surroundings and left the hospital on Nov. 1. A few days later, after no care whatever, because the nurses of a private hospital were afraid to go near this unfortunate man, I found him in a most deplorable condition. The odor from his body was almost insupportable, the whole surface was moist, dusky red, covered with large thick scales attached at their center, and his bed was literally full of desquamated scales. The man was ordered home, where he has been seen every two weeks, and now (February, 1911), the man has gained considerable weight, and with the exception of his face and lower legs the skin is practically normal. The hair has grown again everywhere, except in the anterior portion of the scalp, but the nails are still replaced by elevated conical keratinous masses. This great change for the better can be attributed partly to more favorable surroundings, home cooking and companionship, but principally to the suppression of all external treatment save the application of borated talcum powder. This idea was derived from Dr. Engman and Dr. Mook, of St. Louis, who had found recently in three cases of dermatitis exfoliativa that no treatment at all, or restriction to inert powders, had been followed by cures.

It is a fact worthy of record in this connection that the writer has now under his care three other cases of dermatitis exfoliativa who have all done remarkably well under this desiccating treatment, the explanation of this striking amelioration apparently lying in prevention of bacterial growth, heat and moisture being absent.

Case 52. *Dermatitis medicamentosa.* Male aged sixty-five, merchant.

About eleven days before the outbreak of the skin the man had been given iodalbin, of which he had taken perhaps a half dozen capsules with the idea of helping his arteriosclerosis. (Iodalbin is said to contain 21½% of iodine.) The first symptom noticed was a hemorrhage into the right eye. Two days later a small papule appeared on the left ala of the nose. Other lesions soon developed on cheeks, neck, ear, chin, eyebrows, scalp and back of hands. These lesions were unusual looking. They were whitish, flat-topped, firm, elevated nodules. The top looked macerated as though pus were underneath. On puncture no pus was found, however, but the upper layers of the skin were separated from the highly exuberant underlying papillæ. This was the initial lesion, and each one spread slowly, coalesced with its neighbor and broke down into a firm crateriform sloughing ulcer with rolled up, dirty-white edges. Cultures from unbroken nodules revealed only the ordinary pus germs. General physical examination revealed chronic interstitial nephritis in a greatly debilitated man. The urine contained albumen, but no trace of iodine. Despite energetic treatment, the ulcers continued to spread, necrotize and coalesce until finally practically the whole of the face and back of the left hand became a foul, sloughing, bloody ulcer with greatly elevated, rolled-up, dirty-white surrounding walls. The notable feature of the process was its constant extension without multiplication, but with the strictest adherence of the peripheral walls to the striking clinical characteristics of the original papulo-nodular lesions. Every day found the man weaker and more septic and lesions larger until a few days before death, when the necrosis ceased and healthy granulations appeared. This cutaneous change for the better came too late, however, for the septic absorption had been too severe for a man as badly diseased internally, and death ensued thirty-three days after the appearance of the original papule. At autopsy there were found: (1) Stones in the pelvis and calyces of the right kidney. (2) Pyonephrosis of right kidney. (3) Chronic nephritis and hyperplasia of right kidney. (4) Agenesis of the left kidney. (5) Obliterated left kidney. (6) Arteriosclerosis. (7) Fibrous and verrucous endocarditis of the mitral valve. (8) Slight fibrous endocarditis of the aortic valve. (9) Defective closure of the foramen ovale. (10) Chronic adhesive myocarditis. (11) Hypertrophy and dilatation of the heart. (12) Emphysema and edema of the lungs. (13) Chronic pleuritis, left side. (14) Hydrothorax, left. (15) Ulcer of the stomach. (16) Erosions in the mucosa of cecum. (17) Slight chylous ascites. (18) Cholelithiasis. (19) Streptococcus septicemia. Such a report explains why this man should have been susceptible to an irritant like iodine.

Case 58. *Granuloma fungoides.* Female aged forty-six.

Disease began as a pruritic eczema seven years previously and was treated as an eczema by various physicians until a dermatologist began to be suspicious of a developing granuloma fungoides. Soon after, this doctor's fears were realized, for the chronic red infiltrations of the right popliteal and right mammary regions became more infiltrated and raised above the skin. On entrance to the ward there were numerous, typical, dusky-red, superficially rough and scaly infiltrations scattered over the body. The left foot and left labium were swollen and glands were palpable in the left inguinal and right mammary and axillary regions. Bandaging gave some relief to the edema. A few days later the abdomen began to swell and this condition increased rapidly from day to day. Bullæ now developed on the left leg and thigh, which were now reaching large dimensions and becoming brawny. Flatulency developed and ingestion of food was disagreeable because of the growing abdominal tumor. The left lower extremity and inguinal region were now threatening to break down. Throughout these twenty-three days vigorous x-ray treatment was carried out to the extreme limit and the individual lesions responded well to the influence of the rays. On the twenty-fourth day, after a consultation with Drs. Porter, Harrington, Richardson and Codman, Dr. Porter opened the abdomen and found a large cyst of the left broad ligament containing brownish, turbid fluid. The recovery from ether was good, but lack of appetite and of sleep retarded convalescence. Restlessness and abdominal pain supervened and the following day the patient suddenly died.

The autopsy (Dr. Oscar Richardson) revealed:

A mass in the left inguinal region which shows the operation wound 5 cm. long. This is open and exposes broken down, dirty, grayish, new growth-like tissue. The section of the axillary masses shows tissue similar to that in the groins.

Peritoneal cavity contains a slight excess of reddish cloudy fluid. The serosa of contiguous coils of the small intestine is coated with a slight amount of reddish, granular fibrinous material.

The pelvic cavity contains a large mass of tissue which extends over the brim posteriorly, infiltrating all through the tissues. On section this tissue is grayish-white, encephaloid in character and is continuous with the masses in the inguinal region. This mass infiltrates also the psoas and the muscles of the anterior and abdominal wall.

In the region of the mesenteric and retroperitoneal glands there are smaller and larger masses resembling the tissue already described.

*Diagnosis.* — Pyonephrosis, left. Thrombus in left exterior iliac vein. Edema lower extremity. Slight fibrinous peritonitis. Obsolete tuberculosis of a bronchial gland. Septicemia, streptococcus.

HISTOPATHOLOGY.

*Skin.* — The sections examined were ulcerated to a large extent. The epidermis of the unbroken skin was greatly flattened by the tremendous underlying cellular invasion and the interpapillary downgrowths were sparse, slim or absent. The rete was reduced to a few layers of sickly cells, the granular stratum was for the most part absent and the horny layer was unimportant. The corium was almost entirely occupied by dense, though somewhat scattered, homogeneous masses of mononuclear cells, whose nuclei were unusually large and whose extra-nuclear protoplasm was almost invisible. The supporting reticular membrane was difficult to discern, owing to the density of the infiltrating cells. Curiously enough, one could note a few scattered fibers of elastin, delicate and long and straight in the thickest cellular masses, short and thick in the sparser areas. In the ulcerated portions of the sections the lymphocytic masses extended quite to the free border of the skin.

*New-growth-like mass from the peritoneal cavity.* — The histology of this tissue was similar in all respects to that of the corium of the skin — a dense, almost solid mass of lymphocytes supported by an almost invisible fibrous reticulum.

Case 60. *Lupus vulgaris.* Female aged ten, school.

An unusual type of perhaps fifteen nummular areas on buttocks, thighs, hands and feet. These areas were dull red, free from nodules, very superficial and had recurred several times after various forms of treatment.

She entered the ward for the purpose of allowing the lesions to be excised.

Case 62. *Ichthyosis hystrix.* Male aged twelve, school.

This boy was born blind, deaf and dumb and at the age of one and one-half years developed a strange anomaly of the skin. At entrance, the face, neck, ears, nose, lips, genitals, legs and feet showed lines and plaques of papillary prolongations covered with brown-black integument. The whole skin was dry and harsh to the touch. The terminal phalanges of fingers and toes were enlarged, some were inflamed, and many were without nails. The hair was very sparse and dry and short. (This condition of the hair and nails is suggestive of the congenital and family cases reported by Nicolle and Halipré and by the present writer.[1]

Case 64. *Syphilis.* Male aged twenty-two, student.

Chancre five months previous to entrance followed in four weeks by roseola of two weeks' duration. Later, two months of sore throat and then present rupioid ulcers which dated back one month. These ulcers varied from dime to dollar size, exuded pus and appeared on legs and arms.

Case 69. *Pellagra.* Female aged fifty-two, housework.

This white woman was born in Marblehead, Mass., and had had ten children, of whom six are still living and well. Ten years ago she had bronchitis and has suffered with recurrent attacks ever since. As a young woman she experienced three years of facial neuralgia. The menopause appeared ten years ago, and for the last eight weeks there has been much flatulence and diarrhea. The cutaneous eruption developed on the extensor surface of the forearms as a "pimply rash," which itched severely but soon dried and became scaly. Four weeks ago the skin of the back of both forearms and hands and around the whole wrist was affected. This eruption consisted of vesicles and bullæ on an erythematous base, with suggestion of hemorrhage on the fingers, and the upper brachial margins were absolutely sharp. The tongue was red and swollen and fissured, and the mucous membrane of the lower lip was edematous and covered with brownish crusts along the vermilion border. The labia, vagina and anus presented similar appearances. A biopsy was refused.

The patient was poorly nourished and cachexia was quite pronounced and there had been a loss of weight of twenty pounds during the last five months. There were only seven teeth remaining and these were badly decayed. Pyorrhea alveolaris was present. The knee-jerks were exaggerated. The woman was very weak and listless and her memory was very poor. Anorexia was marked. There were signs of severe bronchitis in the lungs. Before the woman left the ward Dr. Griffin, of Columbia, S. C., examined her and agreed with our diagnosis. Two weeks after leaving the ward the patient died.

In addition to the foregoing patients, there were interesting examples of the following diseases which were severe enough to require hospital care: Dermatitis venenata, 14 cases; eczema, 12 cases; syphilis, 5 cases; varicose ulcers, 4 cases; epithelioma, 3 cases; sycosis vulgaris, psoriasis and scabies, 2 cases each; and lupus erythematosus, herpes zoster, lupus vulgaris, purpura, furunculosis, pityriasis rosea and callositas, 1 case each.

## Medical Progress.

### PROGRESS IN HYGIENE AND STATE MEDICINE.

BY WM. C. HANSON, M.D., AND H. LINENTHAL, M.D., BOSTON.

#### DISINFECTION BY FUMIGATION WITH DRY RESORCIN.

The mode of disinfection which Chalmet[1] describes is practical, inexpensive and claimed to be highly effective as demonstrated by bacteriological tests. The process is as follows: A little resorcin powder is placed on a plate and gently heated by an alcohol lamp; the resorcin vaporizes quickly. For an ordinary room two to three grams of resorcin are sufficient. The room can be aired out after an hour.

Not only does this method disinfect the room, but it is claimed that it acts as a prophylactic, preventing the development of contagious diseases in those who have been exposed to infection. The author advocates the frequent fumigation of the sickroom by this method during the course of the illness. It may also be used for the fumigation of schoolrooms and schoolchildren, since the vapors of resorcin can be inhaled without injury and in many cases with benefit to the respiratory tract.

#### THE VALUE OF DISINFECTION.

From recent bacteriological study Hogarth[2] concludes that persons become infected mainly by direct contact, and that infective material must be comparatively fresh to cause disease. The crucial problem, then, is not in the infectivity of objects, but of patients who continue to harbor active disease-producing germs long after convalescence. To be efficient, the ordinary measures of disinfection require careful revision.

#### THE VALUE OF TERMINAL DISINFECTION.

In a very convincing and stimulating paper Chapin[3] questions the value of terminal disinfection, particularly in such diseases as diphtheria and scarlet fever. The theory of infection by fomites has never had any basis in observation or experiment. It is now well known that the ordinary pathogenic bacteria are not saprophytes and that they begin to lose their virulence and die almost as soon as they leave the body of the host. The danger, therefore, that virulent organisms exist in the patient's room is extremely small and insignificant when compared with the danger of conveying organisms by the nose and throat from the healthy members of the family.

The abandoning of terminal disinfection of scarlet fever and diphtheria in Providence did not in any way increase the number of recurrences of these diseases in the families where one member was ill with either disease.

Terminal disinfection is a costly process, its need is supported neither by theoretical considerations nor by practical results. Furthermore, it withdraws attention from the importance of contact infection and the necessity of personal

cleanliness. The employment of trained nurses by local boards of health to assist in the care of the sick and to instruct by precept and example in methods of personal cleanliness and the management of contagious diseases would be less costly and more effective than terminal disinfection.

### BACTERIOLOGICAL INVESTIGATION OF THE MEMBERS OF THE FAMILY IN DIPHTHERIA CASES.

Nishino [4] examined cultures from the throats of 665 individuals, members of the families of 127 cases of diphtheria. In 41 of these, that is, 6.2%, cultures were positive. Thirty-one of the bacilli carriers were women and 10 were men. Most frequently the carriers were either mothers or sisters, that is, persons who were in close contact with children. The length of time the bacilli persisted in the throats of the carriers varied from two to twenty-five days and was not influenced by local treatment or by antitoxin.

The author concludes that from an epidemiological standpoint the bacilli carriers are of far greater importance than the patient ill with diphtheria, for while the latter is confined in bed, the former move about and come in contact with other people, especially with children. So long as these dangerous carriers are permitted to be about, the disinfection of premises cannot play an important rôle in the prophylaxis of the disease.

### THE SPREAD OF SCARLET FEVER AND DIPHTHERIA IN SCHOOLS.

Chapin [5] gives an account of his results of tabulation and study of cases of scarlet fever and diphtheria for a period of five years. His observations show that the autumnal increase of these diseases is absolutely independent of school attendance. Outbreaks of scarlet fever and diphtheria due to contact in school is the exception rather than the rule. Neighborhood contact outside of school is the more important factor. To guard against the small amount of infection that takes place in school, it is necessary to diminish the chances of exchange of saliva between the schoolchildren. The common drinking cup and roller towel must be done away with and personal cleanliness must be taught by the teacher by precept and example.

### TYPHOID CARRIERS AND THE PROPHYLAXIS OF TYPHOID IN THE ARMY.

Lemoine [6] emphasizes the need of bacteriological study of convalescent cases of typhoid and of cases suffering from gastric and hepatic troubles. For three years he has made blood cultures from all the cases in his clinic suffering from gastric and hepatic disturbances. In 40% of these he succeeded in isolating the Ebert bacillus. The bacteriological laboratory is thus a powerful weapon in the fight against the spread of the disease. But as this is unfortunately not always practical, an educational campaign must be carried on against this disease. The child must be trained to recognize the danger of having the hands soiled by fecal matter. He should be taught to clean his hands after any possible contact till this becomes an automatic act.

### THE ROLE OF CARRIERS IN THE ETIOLOGY OF TYPHOID FEVER.

Lemoine [7] states that the recent attention that has been given to typhoid carriers should not divert attention from the other modes of the spread of typhoid fever. Carriers are, of course, a source of danger, particularly in communities where there is not a proper disposal of sewage. Distinction must be made, however, among the various classes of carriers, those that are ill with the disease, convalescing cases, persons who have been cured, unrecognized cases and finally carriers of typhoid bacilli who never had the disease.

The question of typhoid carriers is but one side of the general question of germ carriers in all infectious diseases. Recent bacteriological research has demonstrated that a number of pathogenic micro-organisms may exist in the natural cavities of the healthy man without being a source of danger either to the carrier or to his environment. Of far greater importance than the healthy carriers are those unrecognized cases of typhoid often mistaken for cases suffering from gastric or hepatic disturbances.

### CHRONIC CARRIERS OF TYPHOID AND PARATYPHOID BACILLI.

Sacquépée [8] is of the opinion that there is no longer any doubt that chronic carriers play an important rôle in the obscure outbreaks of typhoid fever, whether epidemic or endemic. Many authors have variously estimated the number of cases that may be traced to that source, a fair estimate being from 8 to 12% of all the typhoid cases that occur.

The author analyzes all the outbreaks reported in literature which have been traced to typhoid carriers. He concludes that the most frequent mode of the spread of typhoid from carriers is by contamination of milk or other articles of food by the carriers. Less frequently the disease is transmitted by direct contact or by some intermediary agents. It has not yet been demonstrated whether carriers may contaminate drinking water.

In the prophylaxis of typhoid the carriers (since they cause from 8 to 12% of the cases) have to be counted with. The ideal way would be to bring about a bacteriological cure in all cases of typhoid, that is, to have the patient under surveillance till he ceases to discharge typhoid bacilli. Such a method, however, cannot be attained. Many agents and intestinal antiseptics have been used without marked success, more particularly since the typhoid germs lodge in the biliary tract. In some quarters the removal of the gall bladder has been advocated, but in several cases where this operation was done the bacilli that were excreted diminished in number but did not disappear entirely.

It is, of course, impracticable to isolate chronic

carriers, since they may continue to excrete the germs for many years.

The destruction of the germs after they leave the body of the carrier by disinfecting the excreta is the only practicable measure in the prevention of the spread of typhoid by carriers. But even this measure is not always attainable, as it is not an easy matter to get persons to carry it out properly and for a sufficiently long time.

The public must protect itself by strictly guarding its food supply. All persons engaged in the handling of food products, particularly milk, should be under strict permanent supervision.

### THE SPREAD OF CONTAGIOUS DISEASES BY FRUIT.

Sartory and Fillassier [9] examined samples of raisins, strawberries and currants taken from fruit stores where they were exposed for sale. Thirty grams of the fruit were washed in thirty grams of sterile water and bacterial counts were made by means of Petri plates. The number of bacteria found per cubic centimeter in the wash water varied from 1,800,000 to 58,000, according to the cleanliness of the fruit stand, the cleanliness and freedom from dust of the street and to the degree of exposure of the fruit to the street dust.

Second and third washing diminished the bacterial counts to 8,000 and 3,000 per cubic centimeter.

A great variety of bacilli and cocci were isolated, among them being the staphylococus pyogenes aureus and the streptococcus.

The author concludes that the manner of exposing for sale fruit which is to be eaten raw should be regulated so as to protect it from the street dust. The householder should wash the fruit thoroughly in several washings before it is eaten.

### COMMITTEE REPORT ON TYPHOID.

Following a consideration of the situation relative to typhoid fever, a committee of the Massachusetts Association of Boards of Health [10] makes the following recommendations:

1. All cases of typhoid fever must be promptly reported.
2. The State Board of Health should provide for the bacteriological examinations of blood, urine and feces for the presence of typhoid bacilli.
3. A trained agent of the board of health should visit each case for the purpose of seeing that the case is properly isolated and the stools and urine effectively disinfected.
4. The source of infection of every case of typhoid fever should be investigated by the local board of health and a copy of the report should be sent to the State Board of Health.
5. Every house in which there is a case of typhoid fever should be placarded.
6. All cases of typhoid fever should be isolated.
7. All cases of typhoid fever should be given hexamethylene-tetramine throughout the disease and for two weeks after the temperature becomes normal.
8. Patients who in their occupation are likely to infect food should not be released till four successive negative cultures have been obtained from their stools and urine.
9. Bacilli carriers should not be allowed to engage in occupations which necessitate the handling of food.
10. All bacilli carriers should be under the closest supervision of the local board of health.
11. Boards of health having cognizance of a case of typhoid fever on a dairy farm should notify the boards of health of communities to which the milk from that farm is shipped.
12. Privy vaults should not be permitted where there is a public sewer. Where privy vaults are necessary, the board of health should cause them to be properly constructed.
13. Boards of health should institute active measures for fly suppression.

### AN EXPERIMENTAL INVESTIGATION WITH GUINEA PIGS ON THE INFLUENCE OF ALCOHOL ON TUBERCULOSIS.

Kern [11] tried to determine experimentally the effect of alcohol in tuberculous infection in guinea pigs. Several series of experiments were undertaken as follows:

A number of guinea pigs were given daily from 1 to 2 ccm. of 15% alcohol, according to the weight of the animal, for a number of months. An equal number of control animals as nearly alike in weight, age and general condition were kept under exactly the same conditions, but no alcohol was administered to them. Both series of animals were then infected with equal doses of tubercle bacilli into the peritoneum and were kept till they succumbed to the disease. It was found that the animals which had been given alcohol invariably died before those which did not have alcohol. Many other interesting features were brought out in this investigation. The number of animals that succumbed to lobar pneumonia during the course of the investigation was far greater among the alcohol-fed animals than among the control animals. Likewise the young animals born from alcoholic parents gave a higher mortality and showed less resistance to infection than the young ones born from the non-alcoholic parents. The author's conclusions are:

Alcohol, even in moderate doses, diminishes the resistance of the animal organism to infection and hastens the fatal termination in tubercular infection.

Alcohol has a deteriorating effect on the progeny; it shortens the duration of life and unfavorably influences the course of a tubercular infection.

### A REVIEW OF THE PROGRESS MADE IN THE FIGHT AGAINST INDUSTRIAL LEAD POISONING.

Boulin [12] states that it is extremely difficult, if not impossible, to get an accurate number of the cases of lead poisoning that occur in any industry. For lead poisoning is, strictly speaking, not a professional disease, but is a cause of general lowering of the resistance and degeneration of the various body tissues. The slow and gradual accumulation of lead in the tissues and the slow

excretion of the poison produces a degenerative process in the kidneys, blood vessels and nervous system, and renders the individual susceptible to other maladies where the primary causative agent is not recognized.

The principal modes that have been used successfully in England and other countries for the suppression of lead poisoning have been the following:

1. The substitution of other substances for lead in industries where this is possible.
2. Improvement in the hygienic conditions under which the processes are carried on.
3. Systematic medical examination of the workers.
4. Compulsory reporting of cases of lead poisoning.
5. The enforcing of specific regulations in all lead industries.

All these causes have greatly diminished the number of cases that occur in the industries. In some occupations lead has been eliminated; in others, wet processes have been substituted for dry, and dust removal appliances and exhaust have been installed to remove dust and dangerous vapors.

The medical supervision of the workers discloses early cases and eliminates those that are unsuited for the work. Women and young persons are excluded from those processes which are regarded dangerous. The compulsory reporting of cases helps to call attention to sanitary conditions of factories wherein an unduly high number of cases are reported. The regulations insist on certain protective measures for the workers.

### FACTORY INSPECTION AND THE PUBLIC HEALTH. EXCLUSION OF CHILDREN FROM DANGEROUS OCCUPATIONS.

The medical inspection of the factories in Massachusetts aims at the better protection of the health of the community. The state inspectors of health in factory communities acquaint themselves with the hygiene of the town or city, especially in the workmen's quarters, and are constantly investigating tuberculosis and other diseases dangerous to the public health. Within the factory, the inspectors, knowing that tuberculosis of the lungs is a common consequence of overcrowding and exposure to vitiated air and dust, pay special attention to ventilation. In such work the position of the health inspectors is unique, for with their medical knowledge, which is indispensable to the proper enforcement of the statutes, they may appeal to the medical profession on the one hand and to the laity on the other, teaching all that the promotion of public health is a matter which concerns not only the medical profession, but every profession and every person.

Since the health district legislation was enacted in July, 1907, the state inspectors of health, while improving the sanitary conditions in the factories, have made inquiries concerning the health of 78,000 minors under eighteen years of age, and examined physically some 3,500. The children forced to work in a factory are entitled to as great if not greater care than those in the public schools, since many of the factory children are exposed to influences which are far more inimical to health than the conditions to which school children are subjected in schools, and for longer daily periods. One year ago Massachusetts had no law by which children in factories could be protected against poisonous and irritating dusts or against other conditions which might give rise to ill health. To-day, as the result of inquiries made by the State Board of Health, largely through the efforts and observations of the State Inspectors of Health, there is a law which is of inestimable value, permitting as it does work of a dangerous nature by children only on condition that due care is taken by both employer and children to make the occupation a reasonably safe one. The law is so elastic as to be applicable not only to the entire establishment, but to any one department in an establishment, or even to a single child. It involves not those occupations which are dangerous to life or limb, but trades, processes of manufacture, occupations or methods which are deemed by the State Board of Health to be sufficiently injurious to the health of minors as to justify their exclusion therefrom. In its enforcement an educational value is recognized by the State Board of Health and the children are kept at work so far as possible without endangering their health. The law reads as follows:

"The State Board of Health may from time to time upon the written application of any citizen of the Commonwealth, or upon its own initiative, after such investigation as it considers necessary, determine whether or not any particular trade, process of manufacture or occupation, or any particular method of carrying on such trade, process of manufacture or occupation, is sufficiently injurious to the health of minors under eighteen years of age employed therein to justify their exclusion therefrom, and every decision so rendered shall be conclusive evidence of the facts involved therein, except so far as the same may later be revoked or modified by a subsequent decision of the board. Whoever, after being notified that the State Board of Health has determined that a particular trade, process of manufacture, occupation or method is injurious as above stated, employs therein a minor under eighteen years of age shall be punished by a fine of not more than two hundred dollars and not less than fifty dollars for each offense, unless prior to the time of such employment such determination shall have been revoked or modified so as not to include the employment complained of."

In accordance with the terms of this act the State Board of Health declared the processes named in the following schedule to be injurious to the health of children within the meaning of the law, provided that the law "shall not apply to any factory wherein such special measures are adopted as appear to the state inspector of health to be reasonably practicable and meet the necessities of the case":

I. PROCESS INVOLVING EXPOSURE TO POISONOUS DUSTS OR SUBSTANCES.

1. Process in the manufacture of white, red, orange or yellow lead.
2. Processes in the manufacture of lead pipe, solder and plumbers' supplies.
3. Cutting metal articles with a mixture of lead and tin, or lead alone.
4. Processes involving exposure to lead and the dust of plumbago in electrotyping.
5. Processes involving the handling of white lead or lead monoxide (litharge) in rubber factories.
6. Lead paint grinding.
7. Lead working in the manufacture of storage batteries.
8. File cutting by hand.
9. Typesetting, cleaning or handling type in printing offices.
10. Glazing in pottery establishments.

II. PROCESS INVOLVING EXPOSURE TO IRRITATING DUSTS.

1. Process involving exposure to the dust of graphite in the manufacture of stove polish.
2. The operation of bronzing in the lithographing business, and the consequent exposure to bronze powder.
3. Cutlery grinding, and grinding or polishing in the manufacture of machinery, machine parts and metal supplies; and grinding, glazing or polishing on emery or buffing wheels.
4. Cutting, boring, turning, planing, grinding, doming, facing or polishing pearl shell.
5. Talc dusting in rubber works.
6. Sorting, dusting, cutting or grinding rags.

III. PROCESS INVOLVING EXPOSURE TO POISONOUS GASES AND FUMES.

1. Spreading rubber on cloth and the consequent exposure to naphtha in the manufacture of rubber goods.
2. The use of naphtha in cement work in rooms in shoe and rubber factories which are not provided with mechanical means of ventilation where the mixture containing naphtha is allowed to remain in uncovered receptacles.
3. Processes involving exposure to naphtha in the manufacture of japanned or patent leather.
4. Exposure to escape of fumes or gases from lead processes.

IV. PROCESSES INVOLVING EXPOSURE TO IRRITATING GASES AND FUMES.

1. Gassing in textile factories.
2. Singeing in print works, bleaching and dyeing works.
3. Dipping metal in acid solutions.

V. PROCESSES INVOLVING EXPOSURE TO EXTREMES OF HEAT AND OTHER CONDITIONS WHICH PROMOTE SUSCEPTIBILITY TO DISEASE.

1. Melting or annealing glass.

[Approved July 7, 1910.]

During the last year 100 children have been helped by the act: (*a*) 74 by being allowed to continue at their work under certain conditions; (*b*) 10 helped by being transferred to other departments or processes than the one which was deemed injurious; and (*c*) 16 by exclusion from work.

## Book Reviews.

*Primer of Hygiene.* By JOHN W. RITCHIE and JOSEPH S. CALDWELL. Illustrated by KARL HASSMANN and HERMANN HEYER. Yonkers-on-Hudson, N. Y.: World Book Company. 1910.

*Principles of Public Health.* By THOMAS D. TUTTLE, B.S., M.D. Yonkers-on-Hudson, N. Y.: World Book Company. 1910.

These two volumes of the New-World Science Series aim to present the elements of hygiene in simple, popular form. The former is intended for school children of the lower grades. The latter, for children of a larger growth, is avowed by its sub-title to be "a simple textbook on hygiene, presenting the principles fundamental to the conservation of individual and community health." Both are to be commended for their temperate veracity in the treatment of various questions, particularly the use and effects of alcohol and tobacco, which in such books are sometimes sensationally and scandalously exploited. The illustrations possess a considerable degree of pictorial merit, though at times guilty of rather amusing exaggeration. On the whole, the books should prove interesting and beneficial for those to whom they are addressed.

*Education in Sexual Physiology and Hygiene.* A Physician's Message. By PHILIP ZENNER, M. D. Second edition. Cincinnati: The Robert Clarke Company. 1910.

The first edition of this book was reviewed on page 881 of the issue of the JOURNAL for Dec. 8, 1910, and there is nothing to add to that notice. The appearance of a second edition within so short a time seems evidence that the book has been well received by the purchasing public.

*Tuberculosis.* A Treatise by American Authors on its Etiology, Pathology, Frequency, Semeiology, Diagnosis, Prognosis, Prevention and Treatment. Edited by ARNOLD C. KLEBS, M.D. With 3 colored plates and 243 illustrations in text. New York and London: D. Appleton & Co. 1909.

This is the product of eighteen contributors, nearly all of whom are recognized authorities of the subjects of which they treat. All aspects of the tuberculosis problem, social and medical, are considered in this important work.

The book opens with a short historical sketch by Dr. Osler written in his inimitable style. Following this introduction the main subject matter is divided into six parts. At the end of

the volume are eight appendices and a bibliography. The reader is disappointed to find that the articles by Trudeau, Biggs, Von Pirquet, as well as that of Osler, are all very brief. Osler contributes only ten of the seven hundred and ninety-six pages of text. Von Pirquet's article on tuberculosis in children is a little over seven pages in length. Dr. Biggs' sole contribution to the volume is an introductory note to the section on prophylaxis which covers less than two pages. Dr. Trudeau has written less than three pages. This consists of an introduction to the specific treatment of tuberculosis.

One entire chapter of the book, that devoted to primary tuberculosis of muscles and fasciæ, occupies less than half a page and the remainder is left blank. Inasmuch as Cornet in his textbook has collected sufficient data on that rare condition, tuberculosis of the muscles, to furnish over five pages of interesting reading, it seems as if the writer could have filled a printed page instead of seven lines, especially as the editor deemed the subject of sufficient importance to assign a chapter to it.

Ravenel has written on the etiology of the disease and the mode of invasion. He believes that infection through the alimentary tract "occurs in a large proportion of cases," and that the intestinal origin of the disease in children is almost, if not quite, as common as infection through the respiratory passages. These conclusions are scarcely justified by the facts. In the excellent section on the pathological anatomy of the disease, Dr. Hektoen says "that at the present time the general opinion seems to be, however, that while the hematogenous and lymphogenous origin of instances of non-miliary pulmonary tuberculosis cannot be denied, the disease, in the large majority of cases, originates from a primary, air-borne infection of the lungs."

There is an admirable discussion of resistance, predisposition and immunity by Dr. Edward R. Baldwin. This is followed by an interesting chapter by the editor on the frequency of tuberculosis. Dr. Thomas D. Coleman gives a vivid description of the conditions that surround the negro in the South in his chapter on tuberculosis among the dark-skinned races.

Part III of the book is devoted to the symptomatology and diagnosis of pulmonary tuberculosis. This forms nearly one third of the entire volume and is from the pen of Dr. Charles L. Minor. This contains a masterly exposition of the physical signs of phthisis and will be a revelation to the reader familiar only with the meager and stereotyped descriptions found in the textbooks of physical diagnosis. Dr. Minor is an astute and careful clinical investigator, and in his section he has drawn freely upon the thorough knowledge of the disease which he has gained by painstaking study extending over a long period of time. His familiarity with the best that has been written on the subject is evident throughout the article, and many references to the literature are given. Much that is original will be found contributed by Dr. Minor, including a new system of signs for recording physical findings which seems to be an improvement on any now in use.

Dr. S. Adolphus Knopf has an article on public measures in the prophylaxis of tuberculosis which contains much of value to all engaged in the tuberculosis campaign.

There is a notable article on the therapeutic use of tuberculin by Dr. Lawrason Brown, who also writes clearly and concisely on organotherapy, serotherapy and "false specifics."

Dr. Thomas D. Coleman has written a helpful article on the home treatment by sanatorium methods. Strange to say, he does not advocate sleeping in the open-air, and there is too little emphasis on the importance of absolute rest. Paterson's system of graded exercise is described in considerable detail, but the writer fails to state that Paterson's patients were all selected cases who had at least three months of hospital treatment before their admission to the Finley Sanatorium. Furthermore, if a patient developed after exercise a temperature of 99.5° they were placed in bed and as strict a form of rest treatment enforced as if they had had typhoid fever.

Dr. Henry Sewall has contributed an essay on the physiology of climate. He has handled this difficult theme in a satisfactory manner.

Dr. W. Jarvis Barlow has a good section on climatic therapeutics which will be found useful in comparing the advantages and disadvantages of various health resorts.

Unfortunately throughout the entire volume there are no page references to books cited in the text. This throws a needless burden on the readers who wish to consult the authorities quoted. For example, Dr. Minor quoted W. H. Walshe as supporting his position that the typical râle in the incipiency of phthisis is a dry crackle and not a moist râle as has been asserted by recent American writers. Walshe's treatise on diseases of the lungs, heart and aorta is a work of over eight hundred pages and some little difficulty may be experienced in finding the original reference. Incidentally it may be pointed out that Dr. Walshe's name, which recurs many times in the article, is not spelled correctly. As no man in America is more familiar with Walshe's writings than Dr. Minor, we do not believe this error can be attributed to him.

It is to be regretted that so little attention is paid to the rest treatment by the different writers. Trudeau makes the statement that "the great value of rest while the symptoms of activity are present, and relative rest at all times, is as yet not generally appreciated." This is undoubtedly true and an examination of this latest work on the disease shows that some of the leading specialists do not as yet appreciate its importance. Less than a page of this large volume is devoted to the exposition of the rest treatment, while ninety-four pages are given to the specific treatment. Despite the fact that the contributions are of unequal value and that few of the innovations of the editor can be regarded as improvements, we think that the volume is the best work on tuberculosis that has appeared.

THE BOSTON
# Medical and Surgical Journal.

THURSDAY, MAY 4, 1911

*A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.*

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

*All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston.*

*All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.*

*Remittance should be made by money order, draft or registered letter payable to*

101 TREMONT STREET, BOSTON, MASS.

## ARTHURIAN PHYSICIANS.

IN the legendary romances of King Arthur and the Round Table physicians play but a very small part. That there were doctors in the historic days on which those romances are based is unquestioned. As in many primitive communities, however, they belonged to the priesthood and practiced their function of physical healing only as an adjunct or accessory to their sacred duties. The British druids and the Welsh bards were presumably the physicians of Arthur's time, and scanty references to them are still to be found in prose and metrical romance.

In the tale of Ywaine and Gawin is mentioned Morgan the Wise, who "prepared the ointment which restored Owain to a state of health and sanity." Merlin himself was somewhat of a physician, though his medicine partakes more of the nature of magic and incantation, like the charms and spells believed to have such potency in warding off disease or defending from wounds, or like the potion which the old nurse brewed for Tristram and Iseult on their fateful voyage from Ireland.

Quite probably the Morgan referred to above was the same as Morgan Tud, King Arthur's chief physician, who has been the subject of a recent editorial in the *Lancet*. This Morgan Tud is chiefly mentioned in the story of "Geraint, the Son of Erbin," one of the Mabinogion or Welsh folk-tales which compose the "Llyfr Coch O Hergest," or "Red Book of Hergest." This collection of romances, composed in their present literary Welsh form in the fourteenth century, and first translated into English by Lady Charlotte Guest in 1838, form our most valuable and in some respects probably most accurate record of Arthurian times in Wales for they represent, not the later imaginings of French, German or English poets, but original Celtic tales handed down by bardic tradition for several centuries before being put into writing, as was the case with the Homeric epos in Greece.

The story of Geraint in the Mabinogion, upon which Tennyson founded his idyl of "Geraint and Enid," tells how, in the tourney for the sparrow-hawk at Cardiff, Edeyrn, the son of Nudd, was severely wounded by Geraint and repaired for succor to King Arthur, then keeping court at Whitsuntide at Caerlleon upon Usk. "And Arthur gazed a long time upon him, and was amazed to see him thus." And Edeyrn said, "I have met with much trouble, and received wounds unsupportable." And Arthur said, "Let this man have medical care, until it be known whether he may live." "And Arthur caused Morgan Tud to be called to him. He was the chief physician." And Arthur said, "Take with thee Edeyrn, the son of Nudd, and cause a chamber to be prepared for him, and let him have the aid of medicine as thou wouldest do unto myself, if I were wounded, and let none into his chamber to molest him, but thyself and thy disciples, to administer to him remedies. 'I will do so gladly, Lord,' said Morgan Tud." It is particularly interesting in this extract to note Arthur's admonition against intrusive visitors. Morgan's skill, or the *vis medicatrix naturæ*, seems to have been efficacious, for Edeyrn was successfully "healed of his grievous wounds."

Later in the same story Geraint himself is seriously wounded by Gwalchmai (the Welsh Gawain) who, recognizing his previously unknown opponent, brings him straightway to Arthur. Geraint, however, wishes to continue his quest in spite of his injury. "'Whether wilt thou go?' said Arthur. 'Thou canst not proceed now, unless it be unto thy death. He does not go from here until he is healed.' 'I had rather, Lord,' said Geraint, 'that thou wouldest let me go forth.' 'That will I not, I declare to Heaven,' said he." "And Morgan Tud and his disciples were brought to Geraint. Arthur also called Kadyrieith, and ordered him to pitch a tent for Geraint and the physicians. And Arthur and his hosts remained there nearly a month, whilst Geraint was being healed. And when he was fully recovered, Geraint came to Arthur and asked his permission to depart. 'I know not if thou art quite well.' 'In truth I am, Lord,' said Geraint. 'I shall not believe thee concerning that, but the physicians that were with thee.'

So Arthur caused the physicians to be summoned to him, and asked them if it were true. 'It is true, Lord,' said Morgan Tud. So the next day Arthur permitted him to go forth and he pursued his journey."

The pithy directness of Morgan's rejoinder seems rather characteristic of a physician's habit of thought and speech. The episode illustrates that in those days there existed, too, the plucky and rather stubborn patient who is unwilling to give in to his ailments, a type still met and still filling his overruling physician with secret admiration. Arthur's firmness, his unwillingness to believe Geraint's own testimony as to his cure, and his insistence on hearing the doctor's affidavit of recovery, are also characteristic. To them, probably, as much as to Morgan's ministrations, Geraint was indebted for the fact that he was discharged well, not "on request against advice."

In her notes on the story of Geraint, Lady Guest quotes from other contemporaneous sources to show that Morgan Tud's fame was widely diffused through the Celtic world of the time. "His reputation appears to have extended to Brittany, where the inhabitants still call by the name of Morgan Tut an herb to which they ascribe the most universal healing properties." She further writes as follows, in commenting on the office of chief physician:

"The chief physician, from the nature of his office, was necessarily in very constant attendance upon the royal person, and this was carried so far that not only was he unable to leave the palace without the king's permission, but it was ordained by the law of the land that his seat in the hall should be near to that occupied by the monarch. His lodging was appointed him with the Pennteulu, or the master of the household, and he received his linen clothes from the queen and his woolen clothes from the king. He was obliged to supply medicine gratis to all the four-and-twenty officers of the court, except in the case of one of the three dangerous wounds, which are explained to be a blow on the head penetrating the brain, a thrust in the body penetrating the intestines and the breaking of one of the limbs. And for every one of these three dangerous wounds he was entitled to one hundred and eighty pence and his meat. He was to take security of the family of the wounded man (that he should not be prosecuted) in case he should die of the medicine administered to him; and if he neglected this precaution, he had to answer for the consequence. The price of some of his medicaments was established by law. For a plaster of red ointment he was allowed to charge twelve pence, and eight pence for one of medicinal herbs."

This passage, like those quoted from the text, throws interesting light, not only on the medical manners and customs of the time, but on the physician's social status and the conditions of his practice. Insurance against prosecution was not then unknown, but was even enjoined as a regular procedure. The designation of the three most dangerous wounds seems quite in accord with modern regard, especially since, from the nature of the tourneys, where most wounds were received, fractures of the extremities must also often have been compound. Judging from the amount of hard fighting that went on, the chief physician should have been able frequently to charge his maximum fee of $3.60.

These episodes from a long vanished past serve to recall the beginnings of the medical art among our ancestors, the native Britons. Crude and superstitious as it often was, it was not more so than some of the pseudo-medical cults that persist to-day, and it contained the foundation of serious reputable practice. It was, of course, later superseded by the more cultivated science imported from the continent, but it is pleasant to think that at the dawn of our racial medical history still stands the august and venerable figure of Morgan Tud, the Arthurian physician.

## THE MORAL OF THE THREE-LEGGED CHICKEN.

Report from Alton, Ill., states that there was recently hatched in that town a chicken having three legs, on two of which were three toes each, and on the third were two toes. The hen who hatched this monstrosity is said to have killed it as soon as she observed its condition. This action on the part of the hen is similar to that observed in other animals towards the weakly, unfit or aged of their own species, and is probably analogous to the innate instinct of boys to tease and torment the weaklings among their playmates. At bottom this doubtless represents a natural provision for disposing of the unfit, that they may not perpetuate themselves or interfere with the strong. The obvious analogy is sometimes speciously employed as an argument for similar treatment of the unfit of the human species. It should be remembered, however, that in this respect man does not stand on the same footing as the other animals. In this con-

nection may be quoted a pertinent paragraph from the pen of Dr. Benjamin Moore, of Birkenhead, England.

"Do not let us think the less fit will overrun the earth if they be helped up. The exact opposite is the truth; they will overrun the earth if they are not raised up. If the bad environment is made the almost universal one, the lower type of creature in that environment will overrun the higher type. We are one species, we human-kind, and one class cannot rise or fall by itself; we must take the others up, or be dragged down ourselves along with them."

Of course there is a distinction between unfitness due to bad environment and that due to congenital defect, like that of the three-legged chick. The argument, however, holds good for the treatment of the unfit among men on a different basis from that practiced among the lower animals.

## SMALLPOX AND VACCINATION IN CUBA.

IN an editorial in the issue of the JOURNAL for March 23 we commented on the work of the United States Public Health and Marine-Hospital Service in the eradication of smallpox from the Philippine Islands. In the Public Health Report of the service for April 14, an article by Dr. Villoldo describes the similar work done in Cuba, affording "another conclusive proof that it is within the power of any community to eradicate the disease by means of vaccination." Since 1804, sporadic attempts at general vaccination were made in Cuba under Spanish rule, but the mortality from smallpox still ran high, in some years of epidemic amounting to over 1,000 in the single city of Havana. Immediately after the American occupation of the island in 1898, steps were taken to secure vaccination of all the inhabitants. In 1899 there were only 4 deaths from smallpox in Havana; in 1900 only 2. Since September, 1901, 718,406 vaccinations have been performed in Cuba by the United States government, by the quarantine service and by their successors under the native republic. As a result, smallpox is essentially extinct in the island. The credit for this belongs in large part to the efficiency and zeal of the officers of the United States Public Health and Marine-Hospital Service.

## THE PLAGUE IN ASIA.

REPORTS from Moukden, Manchuria, state that the International Plague Conference, which has been in session there since April 3, closed on Friday, April 28. It is believed that results of considerable value have been accomplished. In addition to a consideration of practical methods of suppressing and preventing plague epidemics, the conference has investigated the modes of its transmission and has decided that the pneumonic and the bubonic types of the disease differ only in manner of entrance of the infection, not in etiology. In connection with this aspect of the problem, experimental work of great merit is said to have been reported by the American delegates, Drs. Strong and Teague.

In Manchuria and China the plague is now announced to be essentially at an end. Report from London, however, states that the disease is still extensively prevalent in India, where it is said to have caused 43,508 deaths in February and 95,884 in March, an average of 1,553 deaths a day for the former and 3,093 a day for the latter month.

## MEDICAL NOTES.

CHOLERA AT ST. PETERSBURG. — On April 26 three suspected cases of Asiatic cholera were reported at St. Petersburg, Russia.

ILLNESS OF THE CROWN PRINCESS OF JAPAN. — It is reported from Tokio that the crown princess of Japan has been ill for several weeks with typhoid fever and that her prognosis is now considered very grave.

INCREASED DURATION OF LIFE IN BERLIN. — The average duration of human life in Berlin is reported to be nine years greater than it was in 1880. This is said to be largely due to the decrease of infant mortality and the improvement in general hygienic and sanitary conditions of the city.

GERMAN ABATTOIR IN CHINA. — Report from the United States consul at Tsingtau, China, states that the German government has recently completed the construction in that city of a model abattoir in which is to be prepared all the meat used in the German protectorate of Kiaochow. In connection with the abattoir is an experiment station for research in animal diseases.

TUBERCULOSIS AMONG CHURCH MEMBERS. — The latest bulletin issued by the National Association for the Study and Prevention of Tuberculosis presents figures indicating that the death-rate from all forms of tuberculosis is higher among church members of all denominations than for the general population in the regis-

tration area of the United States. This is held, however, not to be due to any causal or psychologic relation, but to represent probably a difference in accuracy of returns.

Restriction of Indian Opium Traffic. — Report from London states that negotiations between England and China are now in progress at Pekin for the immediate restriction and ultimate cessation of the exportation of opium to China from India. It is believed that this will be an important step in the final suppression of the illegal opium traffic not only in China, but throughout the world. The successful completion of these negotiations, it is hoped, may be announced at the opening of the International Opium Conference at the Hague on July 1.

Diminished Excess of Women in Germany. — The German imperial census of December, 1910, shows an interesting decrease in the excess of females over males in that country. In 1905 there were 1,033 females to every 1,000 males; in 1910 the proportion was 1,026 to 1,000. This change has taken place in spite of the fact that during this period the male death-rate has been 18.1 per 1,000 and the female only 16.2. The male birth-rate must, therefore, have been considerably higher than that of females. Such a condition should be welcome in a military community. Whatever the factors that produce it, the change illustrates the unaccountable automatic fluctuations by which natural process preserves the balance of population.

### BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, April 25, 1911, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 47, scarlatina 34, typhoid fever 5, measles 164, smallpox 0, tuberculosis 63.

The death-rate of the reported deaths for the week ending April 25, 1911, was 17.26.

Boston Mortality Statistics. — The total number of deaths reported to the Board of Health for the week ending Saturday, noon, April 29, 1911, was 206, against 261 the corresponding week of last year, showing an decrease of 55 deaths, and making the death-rate for the week, 15.59. Of this number 110 were males and 96 were females; 199 were white and 7 colored; 134 were born in the United States, 70 in foreign countries and 2 unknown; 45 were of American parentage, 134 of foreign parentage and 27 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 45 cases and 2 deaths; scarlatina, 44 cases and 2 deaths; typhoid fever, 7 cases and 0 deaths; measles, 179 cases and 2 deaths; tuberculosis, 64 cases and 19 deaths; smallpox, 1 case and 0 deaths. The deaths from pneumonia were 31, whooping cough 4, heart disease 24, bronchitis 2. There were 10 deaths from violent causes. The number of children who died under one year was 40; the number under five years, 57. The number of persons who died over sixty years of age was 46. The deaths in hospitals and public institutions were 86.

Reappointment of Dr. Emerson. — The Civil Service Commission has recently confirmed the reappointment of Dr. Nathaniel W. Emerson, of Boston, as one of the trustees of the city infirmary department.

Benefit of Infants' Hospital. — The bridge tournament and pop concert for the benefit of the Infants' Hospital were held last week at Hotel Somerset, Boston, as announced in the issue of the Journal for April 20. It is believed that a considerable sum of money has been realized for the hospital.

Carney Hospital Alumni Association. — The twenty-third annual meeting of the Carney Hospital Alumni Association was held last week at Hotel Bellevue, Boston. The following officers were elected for the ensuing year: President, Dr. P. F. Butler; vice-president, Dr. E. D. Hurley; secretary, Dr. W. R. MacAusland.

Proceedings under Pure Food and Drug Laws. — It is stated that as a result of information filed in the United States District Court at Lowell, Mass., by the assistant district attorney, proceedings will be initiated against the manufacturers of Hood's Sarsaparilla on the ground that it is not, as alleged on the label, "a cure for all diseases arising from impure blood"; and against the manufacturers of "Wild Cherry Soda Water Flavor," on the ground that it does not contain genuine wild cherry, but is adulterated with benzaldehyde and alcohol.

American Breeders' Association. — A conference of the research committees of the Eugenics Section of the American Breeders' Association was held on May 2 and 3 at the Monson State Hospital, Palmer, Mass. This meeting took the place of the usual annual clinic and conference of the hospital. The chairman, Dr. W. N. Bullard,

sketched the work done on inheritance in epilepsy, and reports were presented from each of the committees. Other papers were read by Drs. Davenport and Southard.

Protection of Food on Saturdays. — In the issue of the Journal for March 16, we noted the intention of the Boston Board of Health to enforce in this city the ordinance requiring all foodstuffs exposed for sale to be kept suitably covered for protection from flies, dust and other sources of contamination. A number of marketmen have protested against this enforcement on Saturday afternoon and evening, alleging that their trade is then so much heavier than at other times that to comply with the regulation would make it impossible for them to attend satisfactorily to their customers. The Board of Health, however, has decided that the order must be complied with equally on all days of the week.

### NEW YORK.

Comparative Birth-Rates in New York. — Birth statistics recently given out by the Health Department go to show that what the government has found to be true in Rhode Island, Ohio and Minnesota is also the case in New York City: That foreign-born mothers are almost twice as prolific as native women. In the second generation of immigrants the women are less prolific than those of the first generation. Of the 127,021 children born in New York during 1910, 64,981 were males and 62,040 females. Among the negro children the sexes were almost equally divided, 1,031 boys and 1,007 girls. In one of the typical Jewish districts of the city the birth-rate in the last three years has averaged 54.90 per 1,000 of the population of the district; in a typical Italian district it has averaged 50.47 per 1,000, and in a negro district, 26.65 per 1,000; while in a native American well-to-do residential district, comprising nine blocks, it was only 6.95 per 1,000. It is a well-established fact, however, that the death-rate is much higher in the offspring of immigrants than among the children of native parents.

Hospital Saturday and Sunday Association. — The distributing committee of the Hospital Saturday and Sunday Association met and made the apportionments of its annual collection on April 24. The total amount of the collection was about $112,000, and the committee distributed $94,000; $9,847, in designated gifts, had already been sent to the hospitals specified, and the balance of the money collected had been paid out for expenses. The institutions which, by reason of the amount of their certified free service, were entitled to receive more than $4,000, with the sums awarded, were as follows: The Montefiore Home and Hospital for Chronic Invalids, $9,400; Mount Sinai Hospital, $8,669; St. Luke's Hospital, $5,345; Orthopedic Dispensary and Hospital, $4,786; German Hospital and Dispensary, $4,352; St. Mary's Free Hospital for Children, $4,136; New York Nursery and Child's Hospital, $4,094. While the collection this season was considerably larger than the average, it had been hoped that some $200,000 would be contributed.

Opening of the New Union Hospital in the Bronx. — The movement on the part of the physicians of the Bronx to have an independent general hospital in that borough has already materialized. In this they have been aided by a number of the local churches, and a lease was secured of the building formerly occupied by the Fordham Hospital, one of the city hospitals allied with Bellevue, for which a new building was erected not long since. The new hospital, which is to be called the Union Hospital, was opened for the reception of patients on May 1. It is different from other institutions of the kind in having medical men for its officers, and one of its special features is that all reputable physicians will be welcome to treat their own cases in it. The president of the hospital association is Dr. John F. Holmes, visiting physician to St. Joseph's Hospital for Consumptives; and the vice-presidents, Dr. Nathan B. Van Etten, who is chairman for the Borough of the Bronx in the Medical Association of the Greater City of New York, and Dr. Frederic W. Loughran, of the visiting staff of the Manhattan Eye, Ear and Throat Hospital. Dr. William A. Boyd, president of the Bronx Medical Association, and a number of other prominent physicians of the borough are also directly interested in the new hospital, for which there is a distinct need on account of the very rapidly increasing population in that section of the city.

Progress of the Anti-Vivisection Campaign. — Jerome D. Greene, general manager of the Rockefeller Institute, has issued a statement in which he says that one result of the agitation by supporters of the bill to appoint a commission to investigate "vivisection" in the state of New

York has already gratified those who see the importance of animal experimentation as an instrument of progress in medicine. (This bill is really worse than the other one now before the legislature, which seeks to impose severe restrictions on the practice, in that the commission it proposes, which on its face has a specious plausibility, is, in fact, to be an absolutely biased one, supported, not by the state, but by the anti-vivisectionists.) The hearing on the bill at Albany and the subsequent discussions of the subject among the members of the legislature have made it clear that public opinion, as represented by the newspapers and by legislators, is thoroughly convinced of the indispensable rôle which animal experimentation has already played in the treatment and prevention of disease, of the humanity with which it is generally conducted, and of the importance of allowing such experimentation full scope in the future. The public, Mr. Greene believes, desires only that the same intelligence and humanity govern the campaign now in progress. Legislators and other representatives of public opinion have been unwilling this year to listen to tales of cruelty to animals in experimental research. The false protestations of their sympathy with the aims of experimental medicine which we hear from those urging the passage of the Bayne bill must be interpreted in the light of the foregoing statement. These are the identical persons who have been working for restrictive legislation in the past. Their choice was either to give up the fight or else, by leaving the ranks of the avowed foes of medical progress and masquerading in the ranks of its friends, gain a vantage point from which their original fight for restrictive legislation might be renewed. The proposed commission of seven would include two persons of the anti-vivisectionist party, a senator and an assemblyman (who might well prove to be the sponsors of the bill, and consequently in favor of its backers), two medical men, who are not required to be in sympathy with experimental medicine, and a seventh member chosen at large. No wonder, he says, that the anti-vivisectionists are content to take their chances of securing restrictive legislation after an investigation by such a commission as this. Small wonder, too, that the State Medical Society, as well as the medical faculties, the research laboratories and the departments of public health in the state have protested against the farce that such an investigation might prove, and against the danger to which the public health and the progress of medicine might consequently be subjected through plausible and hasty legislation.

3. Strouse describes the butyric acid test of Noguchi as follows: "One part (0.1 or 0.2 ccm.) of cerebrospinal fluid is placed in a test tube and to this is added five parts of a 10% solution of pure butyric acid in physiologic salt solution; the mixture is heated to boiling and immediately one part of normal sodium hydrate added and the mixture again boiled; in the presence of increased globulin a definite flocculent precipitate occurs, either immediately or within two hours. This definite precipitate must be differentiated from a faint cloudiness which normal fluids may give, but it requires only slight experience to recognize the difference between positive and negative reactions"; and claims that tests for increased globulin in the spinal fluid are easier to perform than is the total cell count, and have practically the same diagnostic value. The butyric acid test of Noguchi is convenient and accurate. The reaction is positive in general paralysis and cerebrospinal syphilis; negative in brain tumor, cerebral arteriosclerosis and psychoses. A positive reaction in a doubtful nervous case is presumptive evidence in favor of the diagnosis being a syphilitic or a parasyphilitic disease of the nervous system. In tabes dorsalis the reaction is present in only 33⅓%. This reaction is positive in all cases of acute meningitis and absent in meningeal irritation without actual inflammation. It is always present in tuberculous meningitis, and its presence is an aid in diagnosis. The absence of the reaction in cases of suspected tuberculous meningitis is of great value in excluding meningitis.

4. Findley urges, in cases of cancer of the cervix, in which doubt exists as to recurrence after a curettage, an exploratory abdominal incision, for a certain though not large percentage of these cases will be found operable who might otherwise be treated only by palliative measures. The author is also an advocate of Gellhorn's method of using acetone for the relief of hemorrhage and fetid discharge. This is as follows: The treatment should, if possible, be preceded by a thorough exocchleation of the ulcerated area. The curetted cavity is then carefully dried and from one-half to one ounce of acetone is poured into the wound through a Ferguson or other tubular speculum, with the pelvis of the patient raised. This should remain in contact for fifteen to thirty minutes. The acetone is then allowed to run out by lowering the pelvis and the cavity packed with a gauze strip soaked in acetone. After leaving the hospital this treatment can be carried on in the office or home two or three times a week. The healthy mucous membrane of the vagina and vulva may be protected by a layer of petrolatum. This treatment has been very efficient and gives great comfort to an otherwise miserable patient.

7. Bevan, in operating in the presence of peritonitis, tests the abdominal cavity with a female glass catheter. The thumb is placed over the open end, the point introduced into the pelvis, the thumb removed for an instant and replaced again and the catheter withdrawn. In this way pus or clear serum can be detected safely in the pelvis or general cavity. He uses wet dressings in all drained cases, and never uses the exaggerated Fowler position because of the very great fatigue which it causes most patients. [E. H. R.]

1. Kümmell points out that, since a tuberculous cystitis and nephritis may run a latent course in the beginning stages of the disease and cause few characteristic symptoms, it is quite common in the case of women to attribute their complaints to a diseased condition of the reproductive organs and to treat them for a long time for such troubles. It is known that gonorrhea in both male and female is an important predisposing etiologic factor in the later development of tuberculosis of the urinary organs. It is often surprising to find so few changes in the urine and a practically normal bladder in many cases of a widely destructive process in the kidneys. Catheterization of the ureter is absolutely essential in diagnosing renal tuberculosis. Spontaneous healing of renal tuberculosis does occur, but as a result of the process there is little if any of the functionating organ left. An early removal of the affected organ offers a more rapid recovery than waiting for an apparent and deceptive spontaneous healing. Transient improvement, at least in subjective symptoms, may be expected with the use of tuberculin injections, but this is in no way permanent and is later followed by real impairment.

3. Nixon considers that gonococcal infections of the kidney are quite rare. Excluding the cases associated with general septicemia and including the author's 2 cases there are 12 authentic cases, 6 pure and 6 mixed. The condition occurs more frequently in men. Hematogenous infection would seem to play a more important rôle than the ascending type. The symptoms are not different from those caused by other organisms. No diagnosis is of value unless the gonococcus can be demonstrated in the kidney. No case of suppuration in the kidney has been proven conclusively to be due to the gonococcus alone; in all probability a mixed infection is present in all cases.

8. David speaks of intermittent hydrarthrosis as an idiopathic hydrops of one or more joints occurring periodically in attacks lasting three to four days and with a course generally extending over a period of several years. The symptoms are typical with individual variations. The onset is usually sudden and often comes in the night, without previous trauma or other known exciting cause. Pain is variable, but stiffness is practically always present. There should be no redness or inflammatory signs. Efforts to cultivate organisms from the aspirated fluid have been unsuccessful. The knee is most commonly affected. Neurotic conditions seem to play the most important rôle in etiology. Some authors believe the condition to be an angioneurotic edema, certainly a neurotic basis is the only demonstrable one in many cases. [E. H. R.]

1. Handemann has made a study in vitro of blood and serum with different sugar contents and its effect upon the growth of bacteria. By his observations he hoped to throw some light upon the disputed question of what is the cause of the increased liability of diabetics to infections. He concludes that blood in vitro with a sugar content of .5–1% forms no better medium for the growth of staphylococci than normal blood. The addition of sugar to blood within limits met in diabetes does not weaken the bactericidal power towards staphylococci. The opsonic index remains the same after sugar. As a result of his work he thinks that the lowered resistance in diabetes is due more to an injury to the cellular elements than to any special property of the blood serum.

4. Büdingen describes and shows a picture of the apparatus he has devised for passive motion in cases that are confined to bed. Also he considers at considerable length the value of passive motions in cardiac cases.

10. Those authors report a rare case of heart block in a child of five years, which turned out at autopsy to be due to a primary tumor of the heart. The pathological report on the tumor, which is very complete, classifies the tumor as a lymphangio-endothelioma of the auriculo-ventricular knot. [C. F., JR.]

1. Kraus and Stenitzer reported in 1909 on the value of an anti-endotoxic serum for use in the treatment of typhoid fever. This report includes some more cases treated with this serum and agrees with the former one in the value of this serum provided that it is used early in the course of the fever. They give it either subcutaneously or intravenously in doses of 20 to 40 ccm. The method of obtaining the serum is not mentioned in this article.

7. Gümbel takes up the subject of kidney decapsulation in a short article, especially in acute nephritis. In cases where other methods have failed and uremic unconsciousness is about to supervene, he favors the operation, as he thinks that the easing of the kidney pressure frequently gives marked relief. He does not consider that it has any effect upon the chronic lesions resulting from the acute nephritis. [C. F., JR.]

4. *EHRLICH, H. *Nail Extension from Urgent Indication.*

3. From an exhaustive study of serum-therapy in meningitis, Schepelmann concludes that the immediate use of a single large dose of serum is more advantageous than that of numerous smaller doses, not only for the attainment of a quick result, but for the avoidance of serum sickness.

4. Ehrlich regards nail extension as a method, not for replacing, but for completing, plaster extension. He believes that in every case it should be employed before any other operative procedure, especially in urgent cases of compression of important vessels or nerves by dislocated fragments of bones of the extremities. He reports an admirable illustrative case from v. Eiselsberg's clinic at Vienna. [R. M. G.]

12. LANGEMAK. *Strangulated Hernia of the Adneza in Infancy.*
13. CREITE. *Primary Tumor Formation of the Nipple.*

1. The author reviews the literature to some extent, pointing out that the possibility of pressure on the ureters by general pelvic prolapse was recognized by Froriep in 1824. He then goes on to show the various possibilities, reporting two cases of his own, in which pressure on the ureters occurred, and concludes as follows: Genital prolapse in women may cause suppression of urine due to pressure on the ureters. The compression may occur within the true pelvis and is caused by the pressure of the intra-abdominal part of the bladder. The place where the pressure occurs is on the last section of the ureter. Compression of the ureter may follow its prolapse through an opening in the muscular pelvic floor, within which the space must be shared with the uterus and with various varieties of cystocele. After the escape of the ureters through the opening in the pelvic floor, they come upon the inverted vaginal wall, within which the space must also be shared with the uterus and cystocele, and compression may result here.

The occurrence of a cystocele makes the lowest part of the ureters form a convex arm with its uretral orifice due to the change in position of the trigonum, which may partly hinder the emptying of the bladder. The article is very well illustrated. [J. B. S., JR.]

REVUE DE MÉDECINE.

MARCH, 1911.

1. LABBÉ, M., AND FURET, L. *Uric Acid Elimination and Alimentation.*
2. *LENOBLE, E., AND AUBINEAUX, E. *Myoclonic Nystagmus. II.*

2. The authors conclude that the dominant and constant factor of this syndrome is nystagmus, which in its simplest form is a "monosymptomatic variety of myoclonus." The syndrome is almost always congenital and often hereditary and occurs frequently in several members of the same family. [L. H. S.]

REVUE DE CHIRURGIE.

APRIL, 1911.

1. *LAUNAY, P., AND SEGUINOT. *Study of Bilateral Simultaneous Tubal Pregnancy, and a Case of Tubal Pregnancy with Three Fetuses.*
2. *COUDRAY, P. *Coxotuberculosis and Its Treatment.*
3. HEULLY, L., AND BOECKEL, A. *A Rare Form of Tumor of the Salivary Glands.*
4. SOLIERI, S. *A Point in the Pathogenesis of Biliary Colic in Some Forms of Non-Calculous Cholecystitis.*

1. The authors collect from the literature fourteen cases of simultaneous bilateral tubal pregnancy, and report a case of their own observation, apparently unique, in which there was a simultaneous pregnancy of both tubes and that on the right showed twins.

2. The writers report, with full microscopic descriptions and photomicrographs, a case of cylindroma of the sublingual gland. [R. M. G.]

BULLETTINO DELLE SCIENZE MEDICHE.

MARCH, 1911.

1. *FERRI, A. *Four Years of Endemic Typhoid.*
2. MODONESI, F. *Post-Diphtheritic Pseudotabes.*
3. *PICCININI, G. M. *Experimental Researches on the Natural Chloro-Iodo-Sodic Waters for Internal Use.*

1. Ferri presents notes and observations, with two schematic figures, on 142 cases of endemic typhoid which he observed in Bologna during the years 1906 to 1909 inclusive. The combined data for this period show a maximum of incidence between the ages of fifteen and twenty and during the month of October; a minimum in April. Of the nine deaths, only one was due to perforation, and none to hemorrhage.

3. Piccinini presents a historic, geologic account of therapeutic waters in general, followed by a study of "Corallo," a diuretic water of Leghorn, with a careful analysis and description of its physical and chemical properties. [R. M. G.]

## Obituary.

### JEFFERY ALLEN MARSTON, C.B., M.D., M.R.C.P., F.R.C.S.

JEFFERY ALLEN MARSTON, who died in London on March 31, was born on Dec. 2, 1831, at Martham, Norfolk, England. He was educated at the University of Glasgow, and in 1854 received the degree of M.D. from the University of St. Andrews. He immediately entered the British Army as an assistant surgeon and rose steadily through all grades of the service until in 1877 he was appointed secretary to the principal medical officer of the British forces in India. In 1882 he became sanitary officer to the Egyp-

tian expedition and was promoted to the rank of deputy-surgeon-general. In 1887 he visited the United States as delegate to the Ninth International Medical Congress at Washington. In 1888 he served as principal medical officer of the British forces in Egypt, and in 1889 was made surgeon-general and transferred to Gibraltar. After retiring from the service, he became president of the Army Sanitary Committee and was made an honorary-surgeon to the king. For the last thirty years he had been a member of the editorial staff of the *Lancet*. His life is typical of the career of the able and successful British army medical officer. He is survived by his widow, one daughter, and several grandchildren.

## Miscellany.

### SANITARY CONDITIONS IN PANAMA.

In a recent issue of a Boston daily paper, Mr. Henry Welles Durham, formerly a resident engineer in the city of Panama for the Isthmian Canal Commission, comments on the fact that at best sanitation and hygiene can only make tropical countries temporarily tolerable and safe for those habituated to cooler climates. The following extracts from his letter refer to a previous communication printed in the same newspaper:

"I notice in your issue for Wednesday evening, April 5, an interview describing conditions in the Canal Zone with as much exaggeration on the side of optimism as was formerly displayed in the other direction by the early detractors of the work of our government on the Panama Canal. While every one familiar with conditions there must be glad to observe the recognition which the great work of our organization is now obtaining, it seems hardly desirable or necessary that this work should be praised with exaggerated statement and actual misstatement. The results that our sanitary work have developed are sufficiently worthy of note to render it unnecessary that they should be brought to the attention of the American people by claims utterly incompatible with fact. Panama is not a health resort and never will be. I have no doubt that your informant has described his impressions accurately. They are those common to all visitors to the Canal Zone, who go there for a few days or weeks during our winter season, especially to those who are visiting a tropical country for the first time. As the writer states, 'Epidemic disease has been banished from the Isthmus.' The risks of malarial fever have been reduced to a minimum, but the climate has not been changed, and never can be. White men from temperate climates can work in such regions only for limited periods without deterioration and the climate is especially hard on white women. I have known of many cases of wives of canal employees whose health was injured by a prolonged stay in the tropics. The *Canal Record* frequently contains, in its obituary notices, names of young women from twenty-five to thirty-five years of age who died on the Isthmus. The health reports with their sick and death rates do not give us a complete history of the case for comparison with health conditions in Massachusetts.

"The death-rate in the Canal Zone as compared with that of other regions is a matter of no significance. It is the death-rate of a picked body of men, and a few women, in the prime of life, when under normal conditions they have no death-rate. Those who contract disease leave the Isthmus, so that their records are not included in those of the permanent population. The work done there by the sanitary department, in rendering it possible to prosecute this great work under fairly healthful conditions, has been marvelous and is worthy of the highest praise. Nothing can be gained by claiming for them that they have done the impossible."

### RESOLUTIONS AGAINST CONSOLIDATION OF MASSACHUSETTS REGISTRATION BOARDS.

Whereas, Senate Bill 193, having for its object the consolidation of the Massachusetts boards of registration in medicine, pharmacy, dentistry, veterinary medicine and embalming into one commission with a single registrar, who shall be intrusted with all the rights and privileges now resting in the several boards, has been given a hearing before the Public Health Committee of the Legislature, has been reported upon adversely, has been recalled and is now in the hands of said committee; and

*Whereas*, the experience of several years has fully demonstrated the efficiency of these boards and their value to the public; and

*Whereas*, the proposed combination would not only lower the standard established by them, but would practically destroy their efficiency; and

*Whereas*, with one minor exception, each of the boards under consideration is more than self-supporting, is of no expense to the commonwealth, and entails no hardship upon any one; now, therefore, be it

*Resolved*, by the members of the Middlesex South District Medical Society, in annual meeting assembled, that any action by the Legislature tending to destroy the individuality and the authority of the above-mentioned commissions will result in deplorable harm to the public, for whose sole welfare they were created.

*Resolved*, that the members of the said Middlesex South District Medical Society do hereby most solemnly and emphatically protest against the enactment of any legislation, as of Senate Bill No. 193, or of any similar bill having for its object the curtailment of the powers of the present boards of registration, as above mentioned.

*Resolved*, that a copy of these resolutions and protest be sent to each Senator and Representative within the limits of said Medical Society by its Secretary.

Walter L. Bond, M.D.,
*Secretary.*

## THE MARIE FEODOROVNA RED CROSS PRIZES.

THE American Red Cross announces, in connection with the International Conference of the Red Cross which will be held at Washington, D. C., in May, 1912, that the Marie Feodorovna prizes will be awarded.

These prizes, as may be remembered, represent the interest on a fund of 100,000 rubles which the Dowager Empress of Russia established some ten years ago for the purpose of diminishing the sufferings of sick and wounded in war. Prizes are awarded at intervals of five years, and this is the second occasion of this character. These prizes in 1912 will be as follows: One of 6,000 rubles; two of 3,000 rubles each; six of 1,000 rubles each.

The subjects decided upon for the competition are:

(1) Organization of evacuation methods for wounded on the battlefield, involving as much economy as possible in bearers. (2) Surgeon's portable lavatories for war. (3) Methods of applying dressings at aid stations and in ambulances. (4) Wheeled stretchers. (5) Support for a stretcher on the back of a mule. (6) Easily portable folding stretcher. (7) Transport of wounded between men of war and hospital-vessels, and the coast. (8) The best method of heating railroad cars by a system independent of steam from the locomotive. (9) The best model of a portable Röntgen-ray apparatus, permitting utilization of x-rays on the battlefield and at the first-aid stations.

It rests with the jury of award how the prizes will be allotted in respect to the various subjects. That is to say, the largest prize will be awarded for the best solution of any question irrespective of what the question may be.

Further information may be obtained by addressing the Chairman Exhibit Committee, American Red Cross, Washington, D. C.

## INTERNATIONAL SANITATION CONGRESS IN PARIS.

EARLY last March it was announced from Paris that an international sanitation congress on Asiatic cholera and bubonic plague was to be summoned to meet in that city in May. At that time the following statement was issued:

"This new convention has seemed necessary because of last year's outbreak of cholera in southern Italy and the present epidemic in Manchuria, which recalls the worst days of the plague in India. These outbreaks, though tragic in themselves, serve a useful purpose by giving an opportunity for experiment with modern methods of relief and prevention. The latest sanitation congress on cholera, yellow fever and the plague was held in December, 1903. Since then scientific progress has been rapid. The most recent discoveries and improvements must be adapted to the new needs, while adhering to the difficult principle — maximum safety with minimum regulation. To facilitate the work of the congress, the government has ordered the permanent committee of the Office International d'Hygiène Publique to outline a program for the discussions. Since its establishment in 1907, this committee has gathered and published complete data on all questions of sanitary organization."

Intelligence as to the exact dates of the convention has not yet been received, but its sessions will probably begin early in the coming month.

## OLIVER CROMWELL'S HEAD.

ANTIQUARIANS in England have been considerably exercised of late over the genuineness of the head of Oliver Cromwell, which has been recently exhibited in London. It is certainly known that after the Restoration, in January, 1661, on the anniversary of King Charles's execution, the bodies of Cromwell, Bradshaw and Ireton, previously buried in great honor, were exhumed, hanged on Tyburn Hill, subsequently decapitated, and the heads impaled on pikes and set up on Westminster Hall. After a time, it is said, Cromwell's head was blown down in a great storm, secreted by a sentry of republican sympathies, and by him handed down as a precious family treasure, subsequently sold to various owners until it came into the hands of one Dr. Wilkinson, great-grandfather of the present possessor. The story seems authentic enough, and the face is said to bear a close resemblance to the portrait of the Great Protector, "wart and all." Whether or no the tale be true and the relic genuine, probably the contemplation of the head, as of other post-mortem material, gives as little idea of the living man, — to use Dr. Holmes's phrase, —as one gets of the Fourth of July from inspection of the fireworks on the following morning.

## ERADICATION OF PLAGUE IN CALIFORNIA.

THE weekly report of the United States Public Health and Marine-Hospital Service for April 21 contains an article on the "campaign against plague-infected squirrels in California," describing the work done by the service in the attempt to eradicate this disease. That ground-squirrels and other small rodents are carriers of plague infection was demonstrated in 1908. Since that time an extensive campaign has been carried on for the extermination of these animals by hunting, trapping and poisoning. A squirrel-free zone has thus been established and maintained around the cities of San Francisco, Oakland, Berkeley and Alameda, on San Francisco Bay; and in addition there has been a general distribution of poison in other cities and counties of California. As a result, not only has the plague disappeared from this state, but there has been a marked diminution in the number of fleas and flies, a diminution in the incidence and mortality of other preventable infectious diseases, and an improvement in building construction and in the general hygienic condition of the community. Disease prevention, like honesty, is not only right, but it is the best policy.

## Correspondence.

### THE AMERICAN MEDICAL ASSOCIATION IN LOS ANGELES.

Los Angeles, April 21, 1911.

*Mr. Editor:* It is difficult for a physician who has lived and practiced in Los Angeles for thirty-six years to adopt the viewpoint of one who has never been here and tell him of the things that would most interest him.

Los Angeles is situated in a valley, with the Sierra Madre Mountains in view just a few miles to the east, and the Pacific Ocean twelve and fifteen miles to the west.

In this valley are, besides Los Angeles, the beautiful city of Pasadena and the seaside cities of Long Beach, Venice and Santa Monica. Between these towns are orange groves, walnut groves and vineyards. Electric cars with ten and fifteen minute service connect all these places, and, in fact, you can get on an electric car in front of your hotel in Los Angeles and be at the ocean in twenty minutes, or be on top of a mountain in an hour.

The physicians and the citizens generally of Los Angeles feel that a great honor is being conferred upon us in giving Los Angeles the privilege of entertaining the American Medical Association.

From what I can learn of previous meetings, preparations for generous hospitality to all have never surpassed the arrangements for this California session.

Monday, June 26, will be devoted to getting guests suitably located, and there will also be sessions of the Arizona Medical Society, of the American Academy of Medicine, American Proctological Society and of the American Medical Editors' Association.

Several of these societies will have their own banquets on Monday evening, but the chief banquet will be that of the American Medical Editors' Association, which will be given at the Hotel Alexandria, and will be a very beautiful and elaborate affair.

Every physician will receive, as usual, on arrival a book giving the program and all the events, both scientific and social, and also containing the coupons for every social function. Of course the physicians of Los Angeles have nothing to do with the arrangements of the scientific program, but we are devoting ourselves entirely to arranging for the social functions, and for the various excursions.

There is an executive committee of ladies, and a committee of one hundred ladies for information and general hospitality. The address of each one of these ladies will be in the telephone directory, which will be in every room in every hotel. These ladies will be ready to answer the call of the wife or daughter of any physician who may be visiting here, and it will be their pleasure to do everything to make this visit a pleasure.

On Tuesday afternoon a tea will be given at the Alexandria. Seventy-five of our local ladies will be hostesses. This will be an opportunity for our wives and daughters here to get acquainted with those from the East.

On Wednesday morning there will be an automobile trip for the ladies, with light refreshments at the Los Angeles Country Club, which is in charge of another committee of ladies. In the afternoon there will be a garden party on the beautiful grounds of Dr. and Mrs. W. Jarvis Barlow. This will be from 4 to 6.30, and it is expected that not only the wives and daughters, but all of the visiting physicians, will avail themselves of the hospitality of this delightful home.

Dr. Barlow is dean of the Los Angeles College of Medicine of the University of California, and president of the Los Angeles County Medical Association.

On Wednesday night the president's reception will be given at the Shrine Auditorium. This will be in all respects a brilliant affair, and will be followed by a ball that will last from 10.00 to 12.00.

Thursday morning the visiting ladies will be given a rest, or, if they desire, Los Angeles ladies will take them in small groups to seaside resorts.

Thursday afternoon, from 4.00 to 6.00, Dr. and Mrs. Norman Bridge will give an al fresco musical in the tropical gardens of their home in Chester Place. It is expected that the physicians as well as their wives and daughters will attend.

Dr. Norman Bridge has a national reputation, and it will be a delight to himself and Mrs. Bridge to make their guests happy.

On Thursday evening from 8.30 to 12.00 there will be an informal smoker and vaudeville performance. While it is intended to especially please the gentlemen, yet, if the ladies will pardon the smoke, they will all be made welcome, and they will find the occasion enjoyable.

It is thought that the scientific program will close on Thursday.

At 11 A.M., Friday the 30th, automobiles will be furnished for all guests, both ladies and gentlemen, for a drive to and through Pasadena, and at noon they will be ushered into the magnificent sunken gardens, consisting of eighty acres, surrounding the winter home of Adolphus Busch. Here will be given, to the accompaniment of the best music that California can furnish, a *Festin del Jardin* (Spanish luncheon). Mr. Busch has given orders to spare no expense. Beeves and sheep will be barbecued on the ground, and the leading Spanish dishes will be served Q. S. This will all be served by waiters in Spanish costume. After the luncheon, lemonade and cigars will be served to the little groups that will be glad to remain listening to the music in this fairyland. *Truvadores* in Spanish costume will go from place to place singing to the music of guitars and mandolins.

Mr. Busch has also left orders that a number of acres of oranges and grape fruit be protected until this occasion, and every guest will be privileged after the luncheon to pluck an orange for himself.

It is thought that five thousand will be served on this occasion, but if there are more they will not be neglected.

At 3.00 o'clock the scene is transferred to the Tournament Arena, where for an hour there will be Roman chariot races that will provide a few thrills even for doctors, who may think they have gotten past the thrilling period. On Jan. 1 of each year, at Pasadena's Tournament of Roses, one hundred thousand gather to see these races. They will then be brought in the automobiles to their hotels in Los Angeles.

After dinner special cars will be provided taking them to entertainments especially prepared for them at the beach cities, and they will be allowed to return home by midnight.

Saturday they will be taken twenty-five miles out at sea to Catalina Island where a typical fish barbecue will be served.

Besides these formal functions, there will be many other entertainments and excursions. San Diego, Riverside, Redlands and Santa Barbara are all clamoring for you.

A retired doctor at Uplands, a beautiful foothill town, thirty miles from Los Angeles, who has a large orange grove, writes to the committee that he is going to keep ten acres of that grove especially for the visiting doctors, and he wants to give them the fruit on that whole ten acres. He desires you all to come out and be his guests for the day.

There are numerous other proffers of hospitality coming to the committee somewhat similar to this. Those who come to this meeting of the American Medical Association will get a more comprehensive idea of Southern California in five days than the man who comes alone can get in five weeks.

Very truly yours,
Walter Lindley, M.D., LL.D.,
*Editor Southern California Practitioner.*

### THE BEST ROUTE TO SEE THE WONDERS OF THE WESTERN SLOPE.

The Dekum Building,
Portland, Ore., April 21, 1911.

*Mr. Editor:* Having observed in your issue of April 13 a communication from Dr. George W. Gay entitled "The Best Route to See the Wonders of the Western

Slope," I would like to add a few words to what Dr. Gay has said there.

In Dr. Gay's third paragraph, in speaking of the trip from Los Angeles to Yosemite Valley, he says there are two ways of going, one through Bakersfield and Fresno and the other by the coast line to San José. He truly says the coast line way is the best. At the time of year that the American Medical Association is going to meet it will be very hot in Bakersfield and Fresno, so it is much better to take the coast line even if a little longer. In going north after leaving San Francisco it is possible to make a side trip either from Ashland, Ore., or from Klamath Falls to Crater Lake National Park. This lake is in the crater of an extinct volcano and is a very wonderful natural scenic attraction.

Any one interested in seeing the orchards in the beautiful valley of the Rogue River near Medford, Ore., would not find a day wasted by stopping off there.

Those who wish to go trout fishing would find good fishing at that time of year either by going to Newport, Ore., from Albany or by a trip up the Mackenzie River to Mackenzie Bridge from Eugene. There are other streams to be reached from Roseburg and Eugene.

From Portland one can make a short side trip to the seacoast or can take a steamer up the Columbia River to see the wonderful scenery of the Columbia gorge.

Dr. Gay speaks in his fifth paragraph about going to Banff from Seattle and then if any one wishes it coming back to Seattle and then to the Yellowstone Park. If I understand his method correctly it means about one thousand miles extra travel. In returning from Alaska one can leave the steamer at Vancouver, B. C., then by rail to Banff and from there down through the Kootenay Lakes to Spokane and from there to the Yellowstone Park without going back to the coast.

I am sure all the visitors will find the doctors in any of these cities extremely hospitable and anxious to promote the pleasure and welfare of those from the East.

Very truly yours,

GEORGE S. WHITESIDE, M.D.

## RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, APRIL 15, 1911.

| CITIES. | Reported deaths in each. | Deaths under five years. | CITIES. | Reported deaths in each. | Deaths under five years. |

## SOCIETY NOTICES.

THE NORFOLK DISTRICT MEDICAL SOCIETY.—The sixty-first annual meeting will be held at the New American House, Hanover Street, Boston, May 9, 1911.

A. H. HODGDON, M.D., *President.* BRADFORD KENT, M.D., *Secretary.*

THE NEW ENGLAND PEDIATRIC SOCIETY. — The sixteenth meeting will be held on Saturday, May 13, 1911, in Sprague Hall, Boston Medical Library, 8 The Fenway, at 8.15 P.M. The following papers will be read: 1 (*a*) "The Successful Passage of an Unusual Foreign Body through the Intestine of a Child; (*b*) The Importance of the X-Ray in the Diagnosis of Obscure Fractures in Children," William Pearce Coues, M.D., Boston. 2. "Vincent's Angina," Edwin H. Place, M.D., Boston. 3. "Anaphylaxis in Its Relation to Pediatric Practice," Godfrey R. Pisik, M.D., New York. Light refreshments will be served after the meeting.

JOHN LOVETT MORSE, M.D., *President.* FRITZ B. TALBOT, M.D., *Secretary.*

ANNUAL MEETING, NEW HAMPSHIRE MEDICAL SOCIETY. — The one hundred and twentieth annual meeting of the New Hampshire Medical Society will be held at Memorial Hall, 21 Centre Street, Concord, Thursday and Friday, May 11 and 12, 1911.

D. E. SULLIVAN, M.D., *Secretary.*

AMERICAN CLIMATOLOGICAL ASSOCIATION. — The twenty-eighth annual meeting will be held at Montreal, Canada, June 13 and 14, 1911. A preliminary day Monday, June 12, will be spent at Saranac Lake.

GUY HINSDALE, M.D., *Secretary.*
Hot Springs, Va.

## RECENT DEATHS.

CLIFTON ELLIS WING, M.D., M.M.S.S., died at Jamaica Plain, May 1, 1911, aged sixty-two years.

EDWIN FARNHAM, M.D., M.M.S.S., retired, died at Cambridge, April 16, 1911, aged sixty-eight years.

## BOOKS AND PAMPHLETS RECEIVED.

# RECENT EXPERIMENTAL WORK ON THE "FUSION" OF NERVES AND ITS PRACTICAL BEARING ON INFANTILE PARALYSIS. REPORT OF A CASE OF INFANTILE PARALYSIS TREATED BY THIS METHOD.*

BY HENRY O. PEISS, M.D., CLEVELAND, OHIO.

(From the Cushing Laboratory of Experimental Medicine, Western Reserve University.)

THIS evening I wish to address you on a subject which I must confess is still imperfectly clear in my own mind, but, on account of the suggestiveness of certain facts that have been brought out in my research, I feel that it might perhaps interest you if I presented a brief summary of certain aspects of the work, so far as it has progressed.

Therefore I wish this report to be regarded as preliminary only, hoping that at some later time I shall have the opportunity to present to this same section the salient points with greater clearness and conviction.

Before it is possible for me to explain the term "nerve fusion," it is necessary briefly to define certain other terms that I am obliged to use. First the term, "nerve pattern." The nerve pattern is simply the anatomical arrangement or grouping of the fibers in the cross-section of a nerve. This arrangement of the fibers has a definite relation to their peripheral distribution. Thus the main trunk of the sciatic, studied high up, consists for the most part of two large funiculi, one of which is destined to become the external popliteal nerve and the other, the internal popliteal nerve. As we follow the nerve down, each of these two trunks is found to redivide into smaller branches, each branch representing the ultimate distribution of the fibers to certain muscles, skin areas, etc.

(Although it is possible by such a cross-section of a nerve to understand the significance of its component parts as regards distribution, it is not possible to recognize from this aspect alone what the function of the individual fibers is, namely, which are motor, which sensory, which vasomotor, etc. To be sure, there is a rough distinction based upon the size of the fibers, the motor fibers usually being quite large and the vasomotor fibers quite small, but as they are all mingled indiscriminately in the individual funiculus, the nerve pattern gives us but little information as to this point.)

Although the main nerve trunk divides into branches and the branches redivide into others, it is not to be supposed that the individual fibers themselves form any division; each fiber is a single branch of a neurone and remains so all through its course. It begins as an axone from its cell of origin in the gray matter of the cord or a ganglion, and, although in its route it may be subject to the many relational diversities as it passes through spinal root, plexus, nerve trunk and peripheral branch, it forms no break or division in itself until it finally arrives at its place of peripheral distribution in its respective end organ, muscle, skin-area or blood vessel. Thus we see that the nerve pattern may change continually as we follow the nerve down toward the periphery, although each fiber maintains both its anatomical and physiological integrity in relation to a given cell.

In considering the subject of anastomosis of nerves, Stoffel [1] recently demonstrated the necessity of distinctly and definitely understanding the nerve pattern of normal nerves. By a series of gross dissections in hardened nerves of a human infant, he worked out the nerve patterns or the topography of the cross-section, as he referred to it, of some of the larger nerves, such as the median and sciatic. That his point is well taken, there can be no question. I mention it here because it suggests one of the main problems with which we are obliged to deal, and this problem is whether we can artificially change the nerve pattern. Such authorities as Langley and Anderson, Kilvington and Osborne and others have maintained that the pattern can be changed under certain conditions, and they refer to such a change of pattern as a nerve distortion. The object of a nerve distortion is apparent. It is hoped by such a means to redistribute fibers which supply a set of muscles or other tissues in such a way as to increase their functional value.

It goes without saying that a change of nerve pattern or a nerve distortion cannot be obtained without, temporarily at least, seriously disturbing the nerve tissues at the point where the distortion is desired, and we must consider the methods by which such a distortion may be gained. I know of only two such methods; one I have already referred to, namely, nerve anastomosis, which consists in suturing different nerves together so as to form new combinations, and the second is the method of which I wish to speak more especially this evening, namely, that of nerve "fusion."

Before defining the term nerve "fusion," it is necessary for me to say a few words as to the salient features of nerve regeneration after division or crushing, because the important points in nerve fusion depend upon certain anatomical features in this process. It is well known that division of a peripheral nerve is followed by a very characteristic process below the point of division. Clinically, the striated muscles supplied by the nerve no longer respond to the will. Experimentally, after the first few days the peripheral stump loses its reaction to mechanical and electric stimuli, and anatomically, after the first week or so, one finds in the stump below the division that the myelin sheaths have broken up, that the axis-cylinders no longer stain and that there takes place within the scar a marked proliferation of cells and nuclei. These proliferating cells are supposed to be from the sheaths of Schwann. Still later the myelin completely disappears and the main characteristic of the scar in the nerve is simply the increased number of cells just

* Presented at the Section of Experimental Medicine of the Cleveland Academy of Medicine, Feb. 10, 1911.

[1] Zeitschr. für Orthop. Chir., Bd. 25, 1910.

referred to. If the separation between the two divided stumps is maintained, some regeneration in the fibers of the peripheral stump will take place, but only up to a certain point, which varies under local conditions. We may ascribe such beginning regeneration to the part taken by collateral nerves which were divided during the original operation and which now offer the fibers in the peripheral stump a new central connection. But practically speaking, we may regard a nerve cut off from the central stump as sufficiently degenerated to deserve the name. Supposing now that instead of trying to keep the stumps separated after division, we resuture at once or, what amounts to the same thing, we tie a ligature about the nerve and immediately remove it. At first the result is just the same as described above in the peripheral stump, but presently we note a great change, for regeneration of the fibers occurs to a marked degree and if the scar is not too great, the process will in most cases go so far as finally to develop a perfect nerve, physiologically and anatomically.

As to the scar that forms at the place of division under this condition of immediate approximation of the stumps, very clear descriptions of its essential features have been offered by those who have studied this subject most deeply, including such authorities as Ranvier, Cajal, Perroncito, Neumann, Stroebe, Bethe and others. Although these authors disagree materially in their interpretation of certain features, they do agree in most of the essential anatomical facts. The first important fact is the proliferation of the nuclei of the cells of Schwann, which I have mentioned above; axis-cylinders, myelin sheaths and other component parts of normal nerve fibers, including the perineurium of the funiculus, practically disappearing in this mass of new cells. These cells are elongated and run in every direction. On account of this proliferation of tissue the nerve here forms a swelling which is sometimes referred to as a bulb or a neuroma. The length of the bulb indicates the length of the scar. Weeks later, the bulb contracts and approximates the size of the normal nerve, and in its interior, regeneration begins from the central stump, the axis-cylinders pushing their way among the proliferated cells and becoming surrounded with new myelin which, in all probability, is also of central origin. Regeneration meanwhile may make some headway in the peripheral stump, and by some process which is not yet definitely understood the regenerated fibers from the central stump passing through the scar join those in the peripheral stump, or mingle with them so as ultimately to form a new and continuous nerve with every anatomical and physiological feature of normal nerves.

I wish now to call your attention to four distinctive points in the formation of this scar which are pertinent to the present problem. In the first place, the perineurium and endoneurium of the crushed nerve are lost in the proliferated mass of cells. Secondly, when the fibers begin to redevelop they do not develop in straight lines or in parallel lines so as to follow the direction that they had in the central stump, but for a considerable time at least they mechanically follow the course laid down by the arrangement of the cells in the scar, and this means that they run in every direction — downward, upward and obliquely and cross each other frequently (Perroncito, Stroebe, Neumann, etc.). This is an extremely important point. Thirdly, as the regenerating fibers push their way between the cells, they present peculiar endings, often forming fibrillæ which branch from various parts of their growing ends (Ramon y Cajal, Poscharissky, Perroncito). Fourthly, and later in the process, these same fibers are seen to rearrange themselves in an extraordinary and striking manner. From the indiscriminate positions which they were obliged to take on account of the mechanical conditions of the proliferated cells, they now form into straight and parallel lines, conforming to their respective beginnings in the central stump. In a word, in the last stage of regeneration in the scar, the nerve fibers tend to form into their original nerve pattern. But not only do the nerves tend to take their original nerve patterns in the scar, but as they pass through it they also tend to seek out their original tracts in the peripheral stump, and this means that each fiber, whether motor, sensory, vasomotor, pilomotor or secretory, takes up its original function. This tendency is usually ascribed to chemotaxis (Langley). Thus we see that the direction of the new fibers in the scar is influenced by two factors according to the stage in the process; first, the factor of new cell formation which guides the fibers in every direction, and later, the factor of chemotaxis which tends to send the fibers into parallel directions and into their original tracts.

Having shown in this summary fashion the salient features of the scar in a divided nerve, I believe you will now be able to understand what I mean by nerve "fusion." Nerve "fusion" is nothing more nor less than a method which attempts to render permanent the arrangement of the fibers in that stage of regeneration when they run in more than one direction. It is a method for taking advantage of the confused nerve pattern of the scar in the transitory stage and fixing that pattern in the hope that, when regeneration is finally completed, the fibers will have grown down different tracts from those which they originally occupied, thus defeating chemotaxis. So in a case of paralysis, if some of the fibers in the nerve are degenerated and their sheaths are empty, the question arises whether the interposition of a proper scar in the course of that nerve may distort its nerve pattern so as to enable the empty tracts to become occupied again with new fibers. Not only this, but we may also inquire whether some of the branches that form on the sprouting ends of the divided axis-cylinders may also be made to enter tracts which have previously been empty, thus gaining not only a new distribution of fibers, but also an actually greater number.

The theoretical basis of nerve "fusion" being

made plain, the next question is, What method may we use to obtain and maintain a pattern of such peculiar characteristics? Before speaking of this method, I must mention one other point which is based upon the researches of others. This point is that the length of the scar is of great significance in governing the amount of regeneration (Howell and Huber, Perroncito, etc.). Thus it is known that a very short scar such as may be obtained by good approximation of the nerve ends will not change the nerve pattern, and that too long a scar will practically prevent regeneration, because of the interposition of too much mechanical resistance. This point, — the length of the scar, — therefore, was a suggestion to begin with, and the thought was not far removed to use ligatures to obtain fusion. With ligatures we could not only crush the nerve so as to produce the necessary scar, but by using more than one we could control the length of the scar by the distance that they were placed apart. Such ligatures, moreover, enabled us to gather more than one nerve into the formation of the new pattern. Finally, by using ligatures of absorbable material, namely, catgut, we could keep the crushing factor under surgical control from the point of view of time, because such a ligature disappears after a few days. In this way the method was evolved and this method consists simply in tying one or more nerves with two catgut ligatures with the intention of producing a sufficiently long scar to cause distortion of pattern. In order to be sure that crushing was produced, we applied a hemostat to the nerve between the ligatures. The ligatures have been placed $\frac{1}{8}$ to $\frac{1}{4}$ inch apart.

As regards the plan of our experiments we have tried several, the two chief ones being, first, the fusion of two adjoining nerves where one has had a large piece excised above the fusion, and, second, the fusion of two adjoining nerves without excision. We have usually worked upon the popliteals because they are easy to approach and supply antagonistic muscles. The animals used were chiefly full-grown dogs. We let the animals run three or four months before testing them.

These tests have been made from two points of view; first, from the point of view of regeneration, and, second, from the point of view of the crossing fibers. As regards the tests for regeneration, it may be stated that our evidence has most clearly shown that it does take place to a marked degree, but of course not in every case. These tests have been clinical, physiological and anatomical.

As regards the tests for nerve crossing, we have been guided, in a measure, by the work of Kilvington and Osborne, who have done their experiments by the older method of combining nerves by suture. Although in a number of cases we have found that impulses will apparently pass through the scar from one nerve to another, we have not been able, as yet, to rule out electrotonus, for we feel that the currents used have been rather too strong. Even so, our negative results are far more numerous than our positive ones. From the anatomic point of view, however, we have demonstrated that the fibers actually cross. But we have not been able to obtain all positive tests in a given case, one case showing histological crossing and no return of function, another showing return of function but no experimental evidence of crossing, etc. Nor have we been able to show, at least to our own satisfaction, that the redirection of the fibers which we can demonstrate anatomically at certain stages remains permanent. Some of the preparations are, however, extremely suggestive, and, taken as a whole, I believe that we have sufficient evidence to justify us in making further experiments along this line.

Besides doing these experiments on normal nerves, we have also been engaged in disturbing the nerve pattern after lesions had been produced in the spinal cord by earlier operations, hoping that by thus emptying some of the nerve tracts by a central lesion we might in the second operation so distort a nerve trunk as to fill up these empty tracts. We have also experimented on the anterior roots directly, and in other cases on the cauda equina, with special reference to paralysis of the tail. The account of these experiments must be postponed for special reports; I merely mention them in passing in order to indicate that the question of nerve "fusion" is not yet solved, even if one can prove that the nerve pattern in the normal can be altered, because after an original paralysis you must deal not only with degeneration of fibers, but also with fatty degeneration of the muscles originally supplied by those fibers, to say nothing of the fact that the empty tracts after a long-standing paralysis tend to become occluded by connective tissue and later to disappear entirely.

Of course the great practical import of such work as nerve "fusion" and nerve anastomosis is its bearing on infantile paralysis. Much has lately been written upon the pathology of this disease, but the points which are of essential importance from a surgical point of view have been known for some time. These points are that the disease affects chiefly the anterior horns of the gray matter, causing a degeneration or disappearance of the ganglion cells located there, with a resulting paralysis which is chiefly motor.

As regards nerve "fusion" for this condition, we can at once see that theoretically the operation might prove to be of value. It is, of course, a grave question as to whether there is any hope if the muscle tissue is degenerated beyond a certain degree, so that the time interval after the original paralysis might prove to be of great importance in considering the fusion; moreover, it cannot be expected that such a procedure could be helpful in every case. But, generally speaking, there are at least theoretical grounds for thinking that nerve "fusion," if properly done, might in selected cases be of some benefit.

As regards the comparative value of ordinary nerve anastomosis by suture with nerve "fusion" as we have described it, I would not like to make any important comparison at present, except to

say this: that although there is no question as to the theoretical value of the older method, such a method would seem to be much more limited in its applicability than the one I have just described, because that method (nerve anastomosis by suture), to be intelligently done, implies an accurate and definite knowledge of the cross-section topography of the nerves, and this knowledge is usually difficult and often impossible to obtain. Nerve "fusion" does not require this. Besides this seeming advantage of "fusion" over suture where two or more nerves are brought together, nerve "fusion" in addition aims to distort the pattern in the individual funiculus, even without the help of a second nerve. This may prove to be of importance. I might also add that on account of the immediate degeneration below the scar it does away with temporary activity of such muscles as may be producing deformity on account of contractures, thus serving the purpose that a tenotomy might serve in other cases; thus while the nerves below the scar are temporarily out of commission, the limb may be placed in a neutral position of best function so that when regeneration is complete, such deformity as existed becomes obliterated.

The work which I mentioned has been in progress for several years, and from our experiments it seemed that we had sufficient grounds to justify us in trying a nerve "fusion" in at least one human case. Such an opportunity arose last fall. The case I chose was not on account of its favorable characteristics, but one which was in a measure quite unfavorable, — the paralysis was not recent and only one important muscle had preserved anything like its normal integrity.

REPORT OF THE CASE.

This case (Y. C.) first seen Aug. 25, 1910. Nothing important in the family history. Child was learning to walk at the age of nine months, when she was taken with an illness lasting about six weeks, losing the use of her legs. Eighteen months later started to walk again and has remained in a crippled state up to the present time, limping badly. Is wearing store braces.

Sept. 16. — Examination.

*Status.* — Well developed and nourished except for legs, which show evidence of paralysis. Patient is very lame but can walk alone. (The left leg shows control of the hip. She can hold the knee extended, but only in external rotation. Hamstrings under control. The foot in a position of equinus of 45°, the tendo achillis being drawn. She can flex and extend the toes and can evert the foot. No power in inversion or dorsal flexion.)

*The right leg.* — She can control the hip and extend and flex the knee in practically normal fashion. She can dorsal flex the ankle and can extend and flex the toes. She seems to have no other control of this right ankle. The foot can be put into marked calcaneus although no permanent deformity has yet resulted. The foot can be extended to only a right angle at the ankle. Stimulation of skin with sharp point over same lower leg and foot shows no anesthesia. This same (right) lower leg examined further with faradic current, using a du Bois Reymond coil (Ludwig) of the vertical type with 10,000 windings of the secondary and a one-pint Daniell cell, and shows the following: The only motor point found is that of the tibialis anticus, half way down the front of the leg. Minimum stimulation for this muscle obtained with secondary at 123 mm. No motor point could be found for the long extensor of the toes, but occasionally with strong stimulation over belly of muscle the toes would dorsal flex. Currents over soleus-gastrocnemius and tibialis posticus so strong as to be unbearable on the observer's fingers produce no response in plantar flexion or inversion respectively. Touching electrode to the sole causes flexion of toes. No response was obtained in the peroneal muscles. Stimulation over peroneal nerve occasionally causes dorsal flexion of ankle.

Knee jerk sluggish on the left and lively on the right.

*Measurements.* — Anterior superior spine to internal malleolus, right, 19.5 inches; left, 19 inches. Circumcumference of thigh at perineum, right, 11 inches; and left, 10 inches. Circumference of calf at maximum point, right, 6¾ inches; left, 7 inches.

The most suggestive thing which can be obtained in the right lower leg is the loss of power in the gastrocnemius-soleus and tibialis posticus, suggesting a marked paralysis of the internal popliteal.

Sept. 17. — Ether operation at Lakeside Hospital (service of Dr. D. P. Allen) [2]: Incision 2½ inches long made on the back of thigh of the right leg, the lower end of the incision being 2 inches above the knee-joint. Biceps freed and the sciatic exposed. At the place exposed, sciatic could be separated into the external and internal popliteal divisions. These two divisions carefully stroked for several minutes with a tenotomy knife until they bled profusely, then squeezed together into a pulp with a hemostat for a distance of ½ inch and tied with two sutures of plain catgut ¼ inch apart (No. 1 size). In squeezing, the ankle dorsal flexed sharply. Skin sewed with catgut. In accordance with a suggestion by Dr. Briggs, the foot was put up in equinus on account of the calcaneus tendency and the plaster run from the toes to the groin.

(On the left foot, tenotomy of the tendo achillis. The peroneus longus exposed, and by making a hole in the interosseous membrane was passed between the fibula and tibia. The tendon passed through from behind and sutured into the tibialis anticus while the latter was on the stretch, so as to hold the foot at a right angle. Tibialis anticus then shortened. Chromicized catgut used for suturing the tendons and plain catgut for the skin. Foot put up slightly within a right angle and slightly inverted.)

Sept. 18, condition good. No temperature. Toes remain pink on both sides.

Sept. 21, condition good. No temperature. On being asked to move the toes of the right foot, she fails to do so.

Oct. 29 (patient at Rainbow Cottage — Convalescent Hospital), plaster removed on both legs. On the right, wound healed by first intention. Sensation and motion tested. Sensation seems present except in the heel, where there is some callus where she does not seem to feel the point of a pin. From a functional point of view, there is no return of power. She cannot move the ankle in any direction nor can she move the toes, but the foot now readily goes into equinus, there being no longer any resistance in the tibialis anticus.

Measured for a brace with double uprights and with rigid ankle-joint to hold the foot in slight equinus. New plaster applied holding the foot in some equinus and varus.

The other foot shows healing by first intention, the foot remaining in varus. Measured for a valgus brace. New plaster. Told not to be allowed to get on her feet.

Nov. 23, child had developed some little sloughs

[2] For the privilege of operating on this case, the author is indebted to Dr. C. E. Briggs, acting surgeon.

on the fourth and fifth toes of the right foot. In trimming back the plaster another slough was produced. The toe sloughs have healed up and the last one is almost healed. There is no return of movement yet in the toes or in the ankle, but a peculiar resistance suggesting beginning tonicity seems to be developing on the surface of the dorsum. At this place, when she is told to attempt movement, a faint twitching is sometimes noticed.

Dec. 2, sloughs have healed. No movement has returned. Tickling and pin pricks are certainly perceptible. Braces tried on.

Jan. 5, 1911, child wearing braces which seem to fit properly. She has no power in motion yet in the right foot. The four outer toes show some swelling and some blueness. Patient stood upon her feet and stands alone. To try a few steps.

Jan. 11, child steps very well on her feet with the braces on. No motion has come into the foot. There is now a peculiar reflex, namely, flexing the ankle causes flexion of the knee and hip. Sensation has returned well, the child feeling sharp objects distinctly.

Jan. 18, distinct motion noted in dorsal flexion. With tickling of the foot she bends her ankle up and outward a few degrees and usually flexes the four outer toes a little. After the foot comes up it goes back into a right angle, but it cannot be stated whether that is due to the elasticity of the tissues or to contraction of the soleus. Child walking a little. Measurements of calves, right, 6½ inches; left, 6½ inches.

Jan. 25, foot to-day shows a distinct improvement. She has very slight motion in plantar flexion. She has slight motion in inversion. She everts quite well and she can both flex and extend the toes. There is also noticeable a peculiar blueness of the anterior part of the foot, extending from the ends of the toes to about 2 inches back to a line where the blueness stops rather suddenly.

Feb. 7, some improvement. She now bends her ankle downwards. This movement is over an arc of 10°. She moves it upwards about 10°, inwards a few degrees and outward about 20°. Her toes can be moved upward and downward. Compared with her condition before the operation she has all the motions of the ankle and foot, and the total amount represented is about the strength represented in the tibialis anticus before the operation. At the present time the tibialis anticus does not stand out, out of proportion to the other muscles. The color in the front part of the foot is much like normal, the blueness having disappeared.

Feb. 16, case brought into the experimental laboratory and the electrical tests tried. The skin, however, was very sensitive so that the tests had to be postponed. Motion tested again. She can evert, plantar flex, and dorsal flex about 15°. Inversion is less. Circumference of calf, 6¾ inches.

In presenting this case only the facts are submitted and no definite conclusions are as yet to be drawn. One thing may, however, be stated with reasonable assurance, namely, that the control of the patient's ankle is now different from what it was before the nerve fusion, although the total amount of power is as yet no greater. A final verdict can only be given when she reaches that stage where no further improvement is going on, when a supplementary report of the case will be made.

In closing, I wish to acknowledge the important assistance which has been rendered to me by Prof. Geo. N. Stewart, director of the laboratory, and Dr. Marine, also of the laboratory. The former has made many valuable suggestions in the physiology of the research, and the latter has done the same from the anatomical point of view.

## A CASE OF HEMIATROPHY FROM SCLERODERMA.*

BY PHILIP COOMBS KNAPP, A.M., M.D.,

*Clinical Instructor in Diseases of the Nervous System, Harvard Medical School; Physician for Diseases of the Nervous System, Boston City Hospital.*

WHILE a moderate amount of asymmetry between the two halves of the body is an ordinary condition, the more extreme degrees, an actual hemiatrophy, are comparatively rare. Congenital hemiatrophy, as a rule, is due to some malformation or defective development of one half the brain occurring in fetal life. Acquired hemiatrophy, which is far more common, is generally due to some cerebral lesion occurring in childhood and is ordinarily associated with infantile hemiplegia. It may also happen that anterior poliomyelitis affects the arm and leg on one side, giving rise to a partial hemiatrophy, but this is rare.

Probably the rarest form of hemiatrophy is that associated with scleroderma, of which I have been able to find only six reported cases. It seems justifiable, therefore, to present this additional case, which is, so far as I know, the only one reported in this country.

David B., aged eighteen, single, a native of Boston, presented himself at the neurological service of the City Hospital in April, 1907. Except for a little "rheumatism" on the father's side, the family history was not remarkable. He had always been well, except for measles and scarlet fever in childhood. He had never used alcohol or tobacco and denied any venereal disease.

He had worked for two years as a metal-worker, handling tin and sheet-iron, but not lead. Two years before coming to the hospital he had had some sharp paroxysmal pain in the left leg, followed by spasmodic clonic contractions of the muscles of the thigh and slowly progressive wasting of the whole leg. At about the same time he noticed some pigmented nodules in the skin on the left side of the epigastrium, on the anterior aspect of the upper third of the left thigh, just below the knee and along the lower inner border of the gastrocnemius. For six months he had had some "drawing" sensations and spasm near the sternal attachment of the abdominal muscles, and for two weeks some spasm and weakness in the left upper arm, especially in the biceps. The left leg had grown progressively weaker. Except for the symptoms above noted, however, he was in good health and able to work regularly. Occasionally, if he kept one position too long or worked in a cramped position, the leg would give out for a few minutes. There was no headache, vertigo or visual disturbance. He slept

* Case presented at the joint meeting of the New York and Philadelphia Neurological Societies with the Boston Society of Psychiatry and Neurology at Boston, Nov. 23, 1907, and at a clinical meeting of the Neurological Section of the Royal Society of Medicine in London, Dec. 15, 1910.

well and showed no mental peculiarities. There were no disturbances of respiration or circulation; the appetite and digestion were good; micturition was normal and the sexual apparatus was not affected. He had noticed no difference in sweating.

On examination, the noteworthy feature was a wasting of the left half of the body. This was not very noticeable in the face, which showed only a moderate asymmetry, such as is often seen, but it was evident in the arm and very marked in the leg. There was also some shortening of the leg, causing a slight inequality in the gait and leading to a slight compensatory tilting of the pelvis and lateral curvature of the spine, and a tilting of the shoulder-girdle in the opposite direction. The left scapula was rotated upwards and outwards in the "angel-wing" position. There was a band of atrophy over the lower ribs, from the fifth to the tenth, apparently involving both skin and muscles and leading to a thinning of the chest wall, so that the pulsations of the heart were very noticeable. This did not extend back of the anterior axillary line. There was much wasting of the muscles, as shown by the greater prominence of the bones about the hip and knee. The left side of the glans penis seemed somewhat smaller. The following measurements,

FIG. 1.

together with the photographs (Fig. 1), will show the degree of atrophy, and the wasting of the chest wall:

| | Right. | Left. |
|---|---|---|
| Semicircumference of head, | 25 cm. | 24 cm. |
| Semicircumference of chest, | 37.5 cm. | 36 cm. |
| Acromion to olecranon, | 38 cm. | 38 cm. |
| Circumference upper arm, | 25 cm. | 23.5 cm. |
| Length of ulna, | 25.5 cm. | 25.5 cm. |
| Circumference fore-arm, | 23.5 cm. | 21.5 cm. |
| Circumference wrist, | 16.5 cm. | 16 cm. |
| Circumference knuckles, | 21 cm. | 21 cm. |
| Anterior superior spine to internal malleolus, | 88 cm. | 85 cm. |
| Circumference thigh, | 44 cm. | 35 cm. |
| Circumference calf, | 32 cm. | 25.5 cm. |
| Circumference foot, | 22 cm. | 21.5 cm. |

The skin upon the left side of the body was thinner, smoother and more translucent. The condition varied and was most marked over the thigh and over the atrophied region of the chest

FIG. 1.

wall. The superficial veins were very apparent and there was very little hair upon the left leg, and less hair over the entire half of the body, even on the left half of the pubes and in the left axilla. The skin was not adherent to the subjacent parts and did not seem to compress them, being fairly elastic. The loss of hair is shown in the photographs, and the patient himself had noted that it had gradually diminished, being formerly as thick as on the right side. In the regions mentioned in the history and indicated

in the diagram (Fig. 2) were a few firm, slightly elevated nodules, brownish-yellow in color, coalescing into a broad, flat mass and freely movable with the skin, of which they seemed to form a part. A few dilated capillaries were seen about them. The patch in the epigastrium was about 10 cm. in diameter, and that on the thigh 10 cm. long by 2 wide. Dr. C. J. White, who kindly examined them, pronounced them scleroderma.

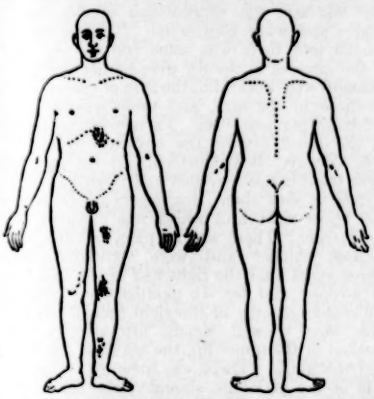

Fig. 2. Distribution of the sclerodermatous patches. April, 1907.

The various movements were performed normally, except that the movements of the left arm and leg were decidedly weaker than those of the right. There was a slight twitching of the lips and tongue, but no hemiatrophy of the tongue. As he stood there were single, quick contractions of the left quadriceps every few seconds which drew up the patella. On electrical testing the muscles on the left side responded more quickly and to a weaker current than the muscles on the right, which I attributed to the greater thinness of the skin. No tests of the electrical resistance, however, were made. Sensation for light contact and vibration ($C^2$, 512 per second) was subjectively a trifle plainer on the left side, but the lightest touch could be felt on the right, and no difference was noted for sensations of heat, cold or pain. The abdominal reflex was livelier on the right side; the plantar, cremasteric and gluteal reflexes on the left; the plantar reflex was of the flexor type. The right knee-jerk was a trifle greater than the left and there was a patellar twitch on that side; the ankle-jerks were equal.

The pupils were equal and regular and reacted to light and accommodation, but the left pupil reacted somewhat sluggishly. The vision in each eye was 20-15. The visual fields and eye-grounds were normal. There was a spur in the left nostril and an enlarged lower turbinate, but the pharynx and larynx were symmetrical and normal. Examination of the hearing and ears showed nothing remarkable. Examination of the lungs showed normal resonance and respiration. The heart was not enlarged and there were no adventitious murmurs, but the apex-beat, as already mentioned, was very noticeable. The pressure was 127 mm. in the right arm and 121 mm. in the left (wide cuff). The blood-count showed 6,200,000 red and 4,600 white on the right, 5,000 white on the left. Hemoglobin, 95. Stained specimens, normal. Urine 1,025, acid, no albumen or sugar; sediment, calcic oxalate crystals, a few uric acid crystals and an occasional leucocyte. A skiagraph showed no noticeable difference in the bones of the leg, in spite of the shortening.

Under galvanism and thyreoid extract (gr. iii–vi, t.i.d.) he showed some improvement. The drawing sensations disappeared, the twitching became much less and his general strength improved. The Röntgen-ray and the high-frequency current were substituted for galvanism later. He has felt well and kept constantly at work. After some months, however, another small sclerodermatous patch appeared to the left of the median line and half way between the xiphoid cartilage and the umbilicus, and the other patches have grown larger. The atrophy has also increased a little both actually and relatively to the other side.

A careful search through the literature of the subject has revealed six other cases of complete hemiatrophy and two of partial hemiatrophy which I will cite briefly:

1. Takács. Man, thirty-two. Family history negative. Always subject to headaches. Two and a half years earlier he began to have tearing pains in the right arm and leg, with some weakness. There was a feeling of tension in the right lower leg. He also noticed that he no longer sweated on that side. The whole right side was smaller, the right eye more deeply set, the right pupil and the right palpebral opening smaller. The right side of the thorax was flatter, and the fingers of the right hand somewhat contracted. The right upper arm was 2 cm. and the right forearm 4½ cm. smaller. The leg was 2½ cm. smaller. The skin on the right side of the face and the back of the right hand was thinner. Sensation and electrical reactions were normal. The trouble was attributed to vasomotor changes.

2. Henschen. Man, forty-six. Family and previous histories unimportant. At the age of fourteen he sprained his left ankle slightly; some time after he had erysipelas in that leg, after which ulcers appeared from time to time on both legs. From this time on he began to have prickling and pain in the left half of the body. Six months later he had severe migraine and changes in the trunk and extremities on the left side, which, after another six months, involved the face. Otherwise he was in good health. At the time of observation there was a marked atrophy of the left face, involving the maxillary bones, extreme atrophy of the left arm and leg, and slight atrophy of the left side of the trunk, which was much greater in certain areas, notably on the lower ribs. In the arm the muscles had wasted very markedly and the bones were

shortened. In the leg the muscles had almost disappeared. The skin on the atrophied areas was very thin, pigmented, smooth and shiny like parchment, and in some places adherent to the bone. The hair and the sweat glands had disappeared. Some of the articulations were ankylosed and the muscular strength was greatly impaired. Cutaneous sensibility was normal except that the affected leg was somewhat more sensitive to cold and electricity. At times there were fibrillary twitchings in the muscles of the affected regions.

3. Steven. Woman, twenty-four. Family and previous histories negative. Eleven years before there was noticed a patch of hardened skin in the right groin and the right hand was swollen and stiff. Similar patches appeared on other parts of the skin and finally on the right temple. A year later the skin ulcerated in various places and then cicatrized. This ulceration lasted three or four years and recurred toward the end of life. At the age of twenty-one an atrophy of the right side of the face and of the right half of the body was observed. Three years later there was marked atrophy of the face, especially of the forehead and chin, and the skin had a brownish, parchment-like appearance. There was marked wasting and contracture of the arm, with claw hand and fibrous ankylosis at the elbow. The arm was 2¼ inches smaller round, there was little motion, and the skin was tightly bound, showing the brownish, parchment-like character with many depressed cicatrices, pink, shiny and with radiating capillaries. The right breast was smaller, and the skin over the abdomen was hide-bound, brownish and parchment-like, with atrophy of the underlying tissue. There was a similar atrophy in the leg, with contractures and changes in the skin. Sensation was normal and she could walk fairly well. About a year later she died as a result of an operation for ovarian tumor. The left motor cortex was somewhat thinner macroscopically. The right anterior horn of the cord was less in size, the motor cells were somewhat degenerated, the neuroglia less dense, and there were perivascular changes in the cord, medulla and pons. There were also degenerated nerve fibers in the cervical and lumbar plexuses.

4. Lunz. Woman, twenty-six. Family and previous histories negative. Some exposure to wet and cold. Paroxysmal dull pain in the right leg for nine years, increasing in severity and duration and followed by wasting. Seven years before, when nursing a child, she noticed that the right breast was smaller and secreted less. For three years wasting of the left cheek with some pain. Pain in the back and limbs for a year. Circumscribed atrophy of the skin, subcutaneous tissue and muscles in the second division of the left fifth nerve. Similar atrophy on the right side, increasing from the trunk downwards. Sensation, motion and electrical reactions normal. Some vasomotor symptoms with coldness and livid pallor of the skin of the lower extremities. The trouble was regarded as neuritis migrans.

5. Pelizaeus. Girl, five and three-quarters. Family and previous histories negative. Injury to head without serious results. Fifteen months before the child began to limp and used the left leg less. For ten months disturbances had been noticed in the skin of the left leg, which gradually increased. The left arm and hand also grew stiff and wasted and stripes were noticed in the skin of the forearm; these stripes were hard and thick and in some places sunken and adherent. The left arm was shorter and smaller and the fingers somewhat contracted. The leg was also wasted and there was some contracture; some of the muscles in the leg were harder and firmer. Changes were noticed in the skin of the leg similar to those in the arm, and there was also some brownish pigmentation. There were no changes in the sensibility or the electrical reactions.

6. Torday. Boy, thirteen. At the age of six right hand became swollen and there was noticed a strip of skin about two fingers in width along the whole right arm which was elevated, paler and harder. There was no pain, but the fingers became thinner and were somewhat flexed. Three years later the right half of the face began to atrophy and for six months there had been noticeable atrophy of the right half of the body. The face showed much hemiatrophy, most marked in the upper lip, the ala nasi, the tongue and the gums. There was atrophy of the right side of the neck and shoulder, the right thorax was flatter and the ribs wider apart. The skin was somewhat darker and the veins visible. The right forearm was 2 to 3 cm. smaller, the hand wasted, the fingers less movable, and the skin very thin, harder and less elastic. On the forearm could be seen some shiny, thickened stripes, transversely wrinkled. The right pelvis was a trifle smaller, the right leg a centimeter shorter and somewhat smaller. The gait was normal, but he had little use of the right arm. There was hemiatrophy of the penis, most noticeable in the glans. There was no reaction of degeneration.

In addition to these six cases I have found two more where the atrophy was partial, but which have been only very briefly reported. The first is cited by Oppenheim, a case of facial hemiatrophy with circumscribed wasting of the soft parts and bones over the back, and hemiatrophy and simple muscular atrophy, without weakness or electrical changes, in the whole right leg. The second case is reported by Osler, of a boy of fifteen, who had a progressive disability of the left arm with wasting of the arm. The scapula and right hand were smaller, the bones were smaller, and the arm was an inch shorter. The skin was sclerosed, hide-bound and pigmented.

Oppenheim also refers to certain cases published by Raymond and Sicard in the *Revue Neurologique* for 1902 (x, 593), of progressive wasting of the arm or leg. Two of these cases were brother and sister. The skin was somewhat wasted, but Dr. Sicard informs me that the skin was smooth in aspect, with a very limited atrophy and not a real scleroderma.

Muscular wasting is a more or less frequent accompaniment of scleroderma. Lewin and Heller, in an analysis of 508 cases, have found it present in only 26; but Hutchinson asserts that it is rarely absent, and Thibierge claims that there is always a certain degree of atrophy except in the mild cases and in those developing in later life. This atrophy he regards as due in part to the enforced inactivity of the limbs and in part to the compression of the vessels and nerves leading to the muscles beneath the sclerodermic area. Méry and Jarisch have found that the sclerotic process may actually invade the muscle itself. The bones may also show some degree of atrophy. This atrophy of muscle and bone is usually most marked in the cases of circumscribed scleroderma, and the compression may be so great in sclerodactylia as to lead to the actual loss of one or more fingers. Much more rarely, however, there may be a primary atrophy of the muscles and bones, independent of any compression and even in parts where the skin is still unaffected (Jarisch, Robert, Thibierge).

In the case just reported, as well as in the cases of Takács, Lunz and Torday, the hypothesis of an atrophy from disuse or from compression seems hardly tenable. In my own case there were no noticeable changes in the skin of the arm, and the skin of the leg, although much wasted, had none of the "hide-bound" character capable of serious compression of the underlying parts. The curious atrophy of the chest wall, apparently very similar to that depicted in Henschen's case, extended beyond the sclerodermic area. The atrophy must, therefore, be regarded as in the main primary.

The cases of facial hemiatrophy present certain conditions analogous to those of general hemiatrophy. All the cases of general hemiatrophy, by the way, except my own and that of Pelizaeus, presented a well-marked facial hemiatrophy, although in Lunz's case the facial hemiatrophy was on the side opposite to the atrophy of the limbs (hemiatrophia cruciata). Volhard's case, although not one of hemiatrophy, is unique. This patient had a left facial hemiatrophy with a peculiar bronzing of the skin over the body in the left upper and right lower quadrants. From the fact that facial hemiatrophy is usually limited to the region supplied by the trigeminal nerve, that it is sometimes accompanied by other symptoms (pain, spasm of the masseters, etc.) indicative of disturbances of the nerve, and still more from the results of autopsy (Mendel[1]), which have shown lesions of the fifth nerve, the majority of neurologists have been disposed to regard it as a nervous affection, and many of the works on neurology class it among the diseases of the trigeminal nerve. The majority of dermatologists, however, are disposed to regard facial hemiatrophy merely as a special localization of circumscribed scleroderma, which not infrequently manifests itself in some special nerve area or possibly in the area of some of the spinal metameres, an opinion which is endorsed by a few neurologists (Cassirer, Collins, Möbius). The most extreme case of facial hemiatrophy I have ever seen — more extreme by far than any depicted in the textbooks — is said to have begun with a patch of morphea on the cheek. Another case seen in its early stages showed merely a band of atrophy, involving the bone, about 4 cm. in width and extending on the left side of the forehead from the root of the nose to within an inch or two of the vertex. This began as a white spot, and the skin in that region was white, with red disk spots and sclerotic. There was some general wasting of the left face apart from the sclerotic area. A considerable number of reported cases of facial hemiatrophy have shown evidences of scleroderma on other parts of the body.

The atrophy, moreover, is not confined to the distribution of the trigeminal nerve. Setting aside the cases of bilateral facial atrophy, a few cases have presented atrophy in other parts of the body. Mendel's case had atrophy of the muscles supplied by the radial nerve on the same side, with degeneration of that nerve. In Debray's and Osler's cases the atrophy had involved the deltoid. I have not searched the literature of facial hemiatrophy to find further cases, but these with the five cases of general hemiatrophy and the two of partial atrophy where the face was also involved are sufficient to establish the fact.

A complete explanation of the hemiatrophy of scleroderma as well as of the circumscribed atrophies, whether of the face or of the body, that occur in this disease must wait until we acquire further knowledge as to the nature of scleroderma itself. Of the various hypotheses as to the nature of the disease, — the thyreoid, the infectious, the vascular and the neurotic, — the latter is perhaps the most probable, but whether, if it be a nervous affection, the disturbance be a gliosis, a lesion of the sympathetic, or an angiotrophoneurosis is a matter not yet removed from the unsatisfactory domain of speculative pathology. The lesions in the anterior horn found by Steven in the only case of sclerodermic hemiatrophy that has come to autopsy were not pronounced and may have been secondary, as Cassirer suggests, while the normal electrical reactions noted in most of the cases show that the changes in the anterior horn if constant, cannot be very marked.

[1] Homén's case, often cited as a case of facial hemiatrophy with autopsy, is rejected by Möbius.

## THE TOWNS-LAMBERT TREATMENT FOR MORPHINISM AND ALCOHOLISM.

BY RICHARD C. CABOT, M.D., BOSTON.

My attention was first called to this treatment two years ago through talks with Dr. Alexander Lambert and Mr. Charles B. Towns, of New York.

I then went to New York and spent several days in Mr. Towns' private hospital, watching the progress of alcoholic and morphine cases at different times of the day and in different stages of their treatment. I was struck at once by the small amount of suffering undergone by these patients as compared with the much severer suffering with which I had been previously familiar in watching the results of withdrawing morphine either suddenly or gradually.

During this visit in New York I also watched the progress of a group of cases under the care of Dr. Alexander Lambert in Bellevue Hospital, and talked the matter out very thoroughly with him. I became convinced at that time that the immediate results of the treatment were remarkable and that its capacity to get a person free from all desire for morphine and alcohol with a comparatively small amount of discomfort made it valuable.

Soon after this visit I sent to the Charles B. Towns Hospital in New York a patient who had been taking morphine for about twenty years. This patient had at times taken as much as 20 gr. of morphine a day, and was just then taking 11 gr. a day. The habit had been previously broken four times, but the desire had not been abolished and the habit had always recurred after a short period. Under the Towns-Lambert treatment this patient was entirely free from the habit and from all desire for morphine in less than ten days. This was eighteen months ago, and there has been no recurrence nor any approach to a recurrence in that time. The patient has been well and happy and is now very actively employed. In this case the discomfort lasted only three days at the beginning of the treatment. At no time was this patient (nor any other whom I have watched) in any danger.

No one who has had any experience with the attempt to break the morphine habit could help being impressed by a case like this, but there still remained in my mind two unanswered questions: (1) Is it possible to accomplish results like this in any considerable proportion of all cases? and (2) How far was the cure just narrated the result of the powerful personality of Mr. Charles B. Towns?

We all know that the psychical element is a considerable one in the treatment of all drug habits, and especially of alcoholism, though most of us, I think, believe that its influence is not very durable in the treatment of confirmed morphinists. Any one who knows Mr. Towns knows one of the most persuasive and dominating personalities in the world, and though I knew that Mr. Towns spent but little time with patients, I was anxious to find out whether the treatment could be carried out with equal success by any one else.

I was much interested, accordingly, in the establishment in November, 1910, of a hospital near Boston in which the same treatment is carried out under physicians who had been trained in the Towns Hospital, in New York. Any physician sending a patient to this hospital is invited to visit his patient frequently and to watch the treatment in all stages and in detail. Nothing whatever about it is secret. Although only six months have passed since the establishment of this institution, I have already seen results sufficient to confirm me in the belief that, aside from suggestion and any notable psychical impression, the treatment has great value, especially in the cure of the morphine habit, and that just as good results can be obtained here as in New York.

The great chance for moral influence over these patients is, I am convinced, after medicinal treatment has achieved an elimination of the craving for the drug. Before that one may waste his time and talk in vain.

Among the twenty-two cases of which I have records of treatment and of the after results, there are ten cases of morphinism, but one of which has relapsed. I prefer to speak at present only of these cases, details of which are given below. In our alcoholics there have been several relapses. Some we have not been able definitely to follow, but several cases have responded to the treatment with marked success. In regard to the value of the treatment in alcoholism, therefore, I have from my own observation as yet no definite opinion, though I feel much interested in it and shall carefully watch results.

Among our morphine cases, the longest period of freedom from symptoms or desire for the drug has been eighteen months (in the case mentioned above). There is also one of four and a half months, three of three and a half months, one of three months, two of two months, and two of one month. The results in these cases are the freedom from any desire for the drug and abstinence from its use.

Of course no one can say that these patients will never return to it, and no one asserts that the treatment gives the patient a new brain and nervous system or fundamentally changes the character which he possessed before he took up the habit.

I see no reason to believe that it is worth while to advise the treatment in cases where the essential diagnosis is *degeneracy*, with morphinism

merely as one symptom of that condition. But when the morphinism is the only sign of degeneracy, or when the patient has no characteristics that would tempt us to use this term at all, there seems to me to be great value in the treatment as compared with any other with which I am acquainted. Perhaps the majority of those who take morphine may be classed as degenerate, but there remains a large number of physicians, happily married women and others who have strong positive interests in life and who have acquired the habit for reasons of a relatively accidental nature under special stress and strain or because of the administration of morphine by a physician. In these cases I believe a considerable percentage of good results will be obtained.

I have here attempted no account of the details of the treatment, since these have been fully given by Dr. Alexander Lambert in the *Journal of the American Medical Association* for Sept. 25, 1909, and Feb. 18, 1911.

Some details regarding the cases of morphine habit are appended herewith.

Case 1. Mrs. O., forty-six years old, had taken morphine "all her life" for menstrual pain and nervous indigestion. At time of entrance was taking 11 gr. a day. Has often taken 20 gr. Treatment (two weeks) in November, 1909; subsequent hysterectomy. No recurrence; excellent health up to April 26, 1911.

Case 2. Mr. P., aged sixty, sent by Dr. Kingsbury, of Needham. Has taken 1 to 3 gr. daily for twelve years. In hospital Dec. 1 to 7, 1910. No recurrence to date (April 26).

Case 3. Mrs. X., thirty-eight years old, has taken 6 to 10 gr. of morphine a day for two years on account of headache. In hospital Dec. 29, 1910, to Jan. 11, 1911. A month later reports that she has not felt so well for many years. Is enthusiastic over results of treatment. Is hard at work and happy; no recurrence to April 26.

Case 4. Dr. S., aged thirty-five, sent by Dr. J. G. Mumford. Has taken morphine for eight years; present dose 5½ gr. hypodermically. In hospital Dec. 29, 1910, to Jan. 15, 1911. Seen three weeks after discharge, feeling better than for a long time. No desire for morphine. Anxious to tell others about the treatment. No recurrence to April 26.

Case 5. Dr. B., aged thirty-seven, has taken morphine four years, averaging 3 gr. a day hypodermically, for the pains of tabes dorsalis. In hospital Dec. 31, 1910, to Jan. 14, 1911. Heard from March 15; well, no desire for morphine, no recurrence.

Case 6. Mrs. O., sent by Dr. Alman Cooper, of Brookline, aged thirty-seven. Had taken morphine for fifteen months on account of menstrual pain. Entered Jan. 7, 1911; stayed three weeks. Heard from April 15; in excellent condition, no desire for morphine.

Case 7. Miss D., aged thirty-five years. Entered Feb. 6, 1911. Had taken morphine for asthmatic attacks (3 or 4 gr. a day) for three years. Seen April 15, feeling finely; no recurrence, no desire for morphine.

Case 8. Miss S., aged twenty-one. Entered Feb. 11, 1911, stayed ten days. She has taken morphine for five years intermittently, averaging perhaps 2 gr. a day. Her statements are very unreliable, but apparently there has been a recurrence since.

Case 9. Mrs. W., aged thirty-nine. Entered hospital Feb. 22, 1911. Has taken 16 to 25 gr. of morphine a day for nine years. April 15 was in good condition; no recurrence.

Case 10. Mr. B., aged forty. Has taken morphine for eight years. Present dose 27 gr. a day; has taken as much as 40 gr. a day. Entered March 12, stayed two weeks. Up to April 26, no recurrence, good condition, no desire for morphine.

I do not use the word "cure" in relation to any of these cases. A much longer period must elapse before any one can be justified in using such a term. All that is here shown is a rapid and comparatively easy arrest of the malady, putting the patient into a good position to begin that reconstruction of his plan of life which is usually necessary.

## A REVIEW OF 214 CASES OF EXTRA-UTERINE PREGNANCY AT THE MASSACHUSETTS GENERAL HOSPITAL.

BY WM. PEARCE COUES, M.D., BOSTON.

Since Tait, in 1883, performed the first operation for extra-uterine pregnancy with the idea of checking hemorrhage, and Janvrin in this country first made the positive diagnosis of unruptured extra-uterine pregnancy in 1886, such a decrease has been brought about by surgery in the mortality of this formerly often fatal calamity as would hardly be believed by those who only lived to see the beginnings of this work. It perhaps brings this home more when we consider that a woman now afflicted with ruptured extra-uterine pregnancy and operated upon has, other things being equal, a four or five times better chance for life than if she had pneumonia.

Shall we operate during the initial shock, or shall we not? That is the question which is the most important consideration in these cases. Symposiums on the subject of late years do not seem to have settled the question.

It is the practice of some surgeons to stimulate their patients and wait for reaction from shock. Others wait without stimulation, and others operate immediately during shock. It is hoped that the following findings upon this and other subjects connected with extra-uterine pregnancy may prove of interest.

I thank the surgeons of the Massachusetts General Hospital through whose kindness I have been allowed to study and report a long series of cases.

*Menstruation.* (*214 cases.*) — One hundred and fifty-nine, or 74.2%, had irregular flowing as a symptom of onset of their extra-uterine pregnancy.

Of these 159, only 15, or 9.4%, had a history of irregular menstruation before the present illness began.

*Age.* — The age was recorded in 183 cases. One hundred and sixty-one, or 87.4%, were twenty-five years or over; 22, or 12.02%, were under twenty-five years; 1, or .54%, was below twenty years, and 7, or 3.8%, were forty years or over.

The greatest number of pregnancies occurred at thirty-two years, viz., 18.

The next greatest number occurred at twenty-eight years, viz., 17. The youngest, 1 case, occurred at

nineteen years, .54%; the oldest, 2 cases at forty-five years, 1.08%.

Sixteen and three tenths per cent of all the pregnancies were at twenty-eight and thirty-two years.

*Number of the pregnancy.* — One hundred and seventy-seven cases with record of this fact.

The greatest number of extra-uterine pregnancies occurred in the second pregnancy, 25.4%; next in the third pregnancy, 24.2%; next in the first pregnancy, 20.9%.

The extra-uterine pregnancy was the first, second, third or fourth pregnancy in 84% of the cases.

*Time after last pregnancy.* (*89 cases.*) — In 32 cases, or about one third, it was under three years since the last pregnancy.

In 16.7% of all the 89 cases it was under one year since the last pregnancy.

In 24.5% of all cases it was under two years since the last pregnancy.

In 35.6% it was under three years since the last pregnancy.

In 58.4% it was under five years since the last pregnancy.

In 6, or 2.8% of the whole 214 cases, it was the second extra-uterine pregnancy.

*Miscarriages.* — One hundred and eighty-five cases with accurate data.

In 61, or 33%, a history of previous miscarriage was recorded.

In 36, or 19.3%, the last uterine pregnancy ended in a miscarriage (about one fifth of the cases).

*Syncope.* — Fifty-six, or 26.1% of 214 cases, had syncope or fainting attacks.

Nine, or 4.6%, had repeated attacks (from two to five attacks).

*Pain.* (*207 cases.*) — *Character of the pain:* Some of the expressions used in describing the initial pain were as follows: Very severe, stabbing, excruciating, cramps, terrible, sharp, intense, shooting, griping, sudden, agonizing and cramp-like. Tenesmus and rectal pain on bowel movement were occasionally noted.

*Data concerning pain:* One hundred and thirty-nine, or 66.1%, had severe abdominal pain recorded.

In 14, or 6.7%, the pain was dull in character.

In only 55, or 26.5%, the onset of the pain was sudden.

Other data thereupon will be found in the table.

Of interest in this connection was Case No. 49.

This patient had dull pain, not localized; general peritonitis was found at autopsy.

*Physical examination at the time of entering the hospital.* (*214 cases.*) — A mass was palpable in 45% of all cases.

In 49 cases the mass was palpable by abdomen as well as vagina.

In 81 cases a mass was palpable by vagina when none was recorded by abdominal examination.

*Vaginal examination.* (*Made in 203 cases.*) — The result of the vaginal examination appears alone in the table.

*Blood.* — One hundred and ten white counts were made.

Thirty-seven, or 33.6%, had a white count under 10,000; 73, or 66.3%, had a white count of 10,000 or over; 36, or 32.7%, had a white count of 15,000 or over; 31, or 28.1%, had a white count of 16,000 or over.

In 24, or 80%, of the cases in shock there was a marked leucocytosis. In only one case of these with this marked leucocytosis, or 4.1%, was a septic condition discovered at operation; that is, in 95.9% of cases the leucocytosis seemed definitely due to a previous hemorrhage.

The lowest white count was 2,000; the highest white counts were two of 45,000 each; the lowest Hb, 9%; this patient was operated upon and recovered.

*Temperature.* — Ninety-three, or 43.4% of the 214 cases, had a temperature of 100 or over. Thirty-one, or 14.4%, had a temperature of 101 or over.

*Mortality.* — Cases from 1888. Two hundred and ten cases operated upon. Mortality, 7.6%.

Two hundred and two abdominal sections; 8 vaginal punctures; 4 patients — no operation was performed.

Two hundred and two abdominal sections, 16 died, mortality of 7.9%. Eight vaginal punctures, 1 died, mortality of 12½%. Two hundred and fourteen cases, whole number, 17 died, mortality of 7.9%.

In three of the cases that died after operation peritonitis was present at operation.

In one, fatty degeneration of heart and liver, and cystic degeneration of pancreas.

In one, interstitial nephritis. (One of the three had peritonitis present at operation.)

Excluding the three cases of peritonitis found at operation, and the case with degeneration of heart, liver and pancreas, we have a mortality of 5.8% in 206 operated cases since 1888.

*Tubes.* (*202 abdominal sections.*) — In 93, or 46.03%, the right tube was the seat of the pregnancy.

In 90, or 44.5%, the left tube was the seat of the pregnancy.

In 19 cases, or 9.4%, the pregnant tube was not definitely identified or described as right or left in the record.

*Pathological report.* — There were 143 pathological reports. In 76 cases it was possible to differentiate by the report the part of the tube the seat of pregnancy.

Ampulla pregnancy was found in 50, or 65.7%.

Isthmic pregnancy was found in 14, or 19.4%.

In 9, or 11.8%, pregnancy was recorded as in the middle of the tube without stating definitely whether isthmic or ampulla pregnancy could be differentiated.

Interstitial pregnancy in 2, or 2.6%, was recorded.

*Fetus.* — Two hundred and ten cases, all the cases operated upon.

The fetus was found in 51, or 24.2%, of the cases.

The fetus was found in a tube in 15, or 30%, of 51 cases.

It was found in the abdomen in 10, or 20.2% of the 51 cases.

In 26, or 50.5% of all, the record stated that the fetus was found without giving particulars as to the location.

In one case, or .49%, a double extra-uterine pregnancy was found.

Two cases of interstitial pregnancy were recorded. One recovered, 1 died, mortality 50%.

*Disease of tube and ovaries.* (*202 cases.*) — In 34, or 16.7%, the opposite tube was diseased; in 70, or 34.6%, adhesions were found; in 31, or 15.3%, there was a cystic ovary; in 19 the cystic ovary was on the opposite side; in 12 the cystic ovary was on the same side; in 4 both ovaries were cystic — 202 cases.

In 70, adhesions were present; 31 cystic ovaries; in 34 the other tube was diseased; in 34 the last pregnancy ended in miscarriage. One hundred and sixty-nine cases, or 83.6%, had one of these troubles.

*Tubal abortion and ruptured tube.* — One hundred and fifty-two cases with accurate data. In 119, or 78.2%, the tube was ruptured; 26, or 17.1%, were tubal abortions; 7, or 4.6%, were unruptured.

There were three cases of extra-uterine pregnancy at or near full term. All these were operated upon. One eight to nine months, the sac was stitched to the abdomen; recovered. One nine months, placenta removed; recovered. One eight months, sac packed, died, mortality, 33⅓%.

*Hemorrhage at operation.* — Active bleeding was

found going on in 9 cases of the 202 abdominal operations, 4.4% of the cases.

Clotted blood in 104 cases; fresh blood free in abdomen, 79 cases; 183 cases, or 90.4%.

The amount of blood in the abdomen was in some cases described as follows: Very large amount, 1 to 2 quarts, 1½ quarts, completely filled, 1 quart; filled with liquid and clotted blood; three double hands full of clot removed, abdomen full of fresh blood; many quarts; 2 quarts of blood and clots, 1 quart, 2 quarts; pelvis full of blood — 1 quart, pelvis full of blood — wash basin full.

*Shock.* (*210 cases operated upon.*) — Fifty-two, or 24.2%, of the cases were in shock. Immediate operation in shock, 28 cases. Seven died. Mortality, 25%. Delayed operation, 24 cases. Two died. Mortality, 8.3%. (Both of these had peritonitis at time of operation.)

One case died of shock without operation.

*Immediate Operation in Shock.*

I. Aged forty-four. Immediate operation. Marked shock. Interstitial pregnancy, temperature 99.4, pulse 135, respiration 48. Pulse hardly perceptible at wrists, bloody fluid and clots in abdomen, tube ruptured, tear extending from near the end of tube into the cornua of uterus; never recovered from shock, died same day.

II. Aged thirty-two. Immediate operation. Shock. Temperature 100, pulse 140, respiration 37, white blood count 30,000, Hb. 47%; tube ruptured, no fresh blood in abdomen, distended intestine, drained, markedly distended after operation, vomited without effort large amount of dark fluid. Stomach washed out, escape of large amount of gas and dark brown fluid, softening stomach. Died with signs of resolving pneumonia at base. Acute dilatation of stomach.

III. Aged thirty. Immediate operation. Shock. Temperature 100, pulse 150, respiration 20. Tube ruptured, abdomen filled with clots and blood, no other pathological conditions found at operation. Died of shock same day.

IV. Age? Immediate operation. Shock marked. Temperature 100.5, pulse 140. Tube ruptured, great deal of free and clotted blood in abdomen, no other pathological conditions discovered at operation. Died next day, never recovered from original shock.

V. Aged thirty-eight. Immediate operation. Cyanotic; in shock. Temperature 102, pulse 132, white blood count 20,000. Right tube ruptured, markedly distended, clots and bloody fluid in abdomen, intestine distended, drained. Died next day.

VI. Aged forty. Immediate operation. Shock. Temperature 99, pulse 130, respiration 16. Tube ruptured, free blood and large amount of clot in abdomen, no other pathological conditions found at operation, tube found dry — left in. Death caused by hemorrhage from the tube at site of pregnancy. Patient reacted well from operation, when blood pressure returned to nearly normal; it is probable that second hemorrhage took place. Died in three days. Pathological report, — extra-uterine pregnancy, rupture and extensive hemorrhage, small parovarian cyst.

VII. Aged twenty-nine. Immediate operation. Profound shock. Temperature 100.5, pulse 120, respiration 40. Tube ruptured, skin ashen, water and air hunger, dark clotted blood gushed out; no other pathological conditions discovered at operation. Died of shock next day.

*Delayed Operation in Shock.*

VIII. Aged twenty-five. Temperature 101.2, pulse 108, respiration 24; good pulse and color, abdomen negative, excellent appetite, three days after entrance after examination, sharp pain, shock, thirsty and pale. Operation one day after shock came on, tube ruptured, free blood in abdomen, pelvis sloughy; lower abdomen full of rather bright fluid blood. Twenty-eighth, wound reopened, greatly dilated stomach, filling abdomen, general peritonitis. Original focus in right tube.

IX. Aged thirty-four. Temperature 100.4, pulse 108, respiration 20. Waited one day in shock, infused at operation, prostrated. Temperature 105, peritonitis present at operation. Died.

*Cases Operated Upon Not in Shock.*

X. Aged twenty-eight. No shock. Temperature 100.8, pulse 120, operation delayed some hours, tubal abortion, four weeks' illness, large masses of clot free in abdomen, gush of stale blood, peritonitis recorded, failed with distention and vomiting.

XI. Aged thirty-four. Temperature 102, pulse 128, respiration 32. General condition good, umbilical hernia, enormously fat, waited one day, no change in patient's condition during night. Incision opened into a blood cyst, wall of sac covered by peritoneum, mass like ovum size of apple removed; 1 to 2 quarts of blood gushed out. Autopsy showed fatty degeneration of heart and liver, cystic degeneration of pancreas. Extra-uterine pregnancy.

XII. Aged thirty-four. Temperature 99.8, pulse 92, respiration 20. One-fourth per cent albumin in urine, waited one day, no shock, eight months' fetus found, tumor covered by peritoneum, child extracted, sac packed with gauze, pint of blood lost, failed, died in four days. Shock? Record states, "Not enough bleeding to cause death."

XIII. Aged thirty-two. Temperature 100.2, pulse 93, respiration 39. One-tenth per cent albumin in urine, few granular casts. Bowel distended, tympanitic, no shock recorded, operation after two days. Drained, left tube probable rupture; clot quite adherent to intestine, much free blood. Distention steadily increased after operation; died. Sepsis?

XIV. Second extra-uterine pregnancy. No shock. Temperature 96.7, pulse 80, respiration 24. Operation two days after entrance, careful examination of records shows no shock despite temperature. Tubal abortion, great amount of old blood clot in abdomen; adhesions drained, patient got out of bed, then sank, failed from this time. Died. Purulent general peritonitis found at autopsy.

XV. Aged thirty-two. Temperature 98.4, pulse 110. No shock recorded. Operation thirteen days after entrance, tube ruptured at operation, fetus free in pelvis, other tube removed, drained, failed, with distention, nausea, weak pulse. Autopsy showed fibrous peritonitis. Early interstitial nephritis, pulmonary edema, pleural effusion.

XVI. Aged thirty-four. Temperature 99.5, pulse 88, respiration 20. No shock recorded. Italian, poor history, abdomen negative; first operation three days after admission, vaginal puncture, dilating and curetting, old fibrinous clots and fresh clotted blood removed. Drained. After operation, vomited constantly, diarrhea, distended, tender, rigid. Second operation, laparotomy, dark bloody fluid in pelvis, bowel much injected, many light adhesions. Died.

XVII. Not operated upon. Aged thirty-seven. Temperature 100.2, pulse 84, respiration 24. History of irregular menstruation. Sudden very severe pain and collapse one month ago. Entered hospital, in good condition, well-nourished, did not appear sick. Reported for sudden collapse, patient blanched, cold, extreme pain, clammy extremities, lips purple, nose and ears cold, no pulse at wrist. Temperature 96.8;

given stimulation, rallied; later in afternoon no pulse at wrist, vomited everything. Operation not advised. Died.

TABULATED STATISTICS OF EXTRA-UTERINE PREGNANCY.

*Menstruation (214 Cases.)*

Irregular, 74.2%. Irregular before present illness, 9.4%.

*Miscarriages (185 Cases).*

33% previous miscarriage.
19.3% last uterine pregnancy ended in miscarriage.

*Syncope (214 Cases).*

26.1% of all cases; 4.6% repeated attacks.

*Tubes (202 Abdominal Sections).*

46.3% right; 44.5% left; 9.4% not identified.

*Pathological Reports (76 Cases).*

Ampulla pregnancy, 65.7%
Isthmic pregnancy, 19.4%
Interstitial, 2.6%

*Tubal Abortion and Rupture Tube (152 Cases).*

78.2% tube was ruptured.
17.1% tubal abortions.
4.6% unruptured.

*Age (183 Cases).*

87.4% over twenty-five.
12.02% under twenty-five.
3.8%, forty or over.
Youngest, nineteen years.
Oldest, 2 at forty-five years.
Greatest number at thirty-two years, 18.
Next at twenty-eight years, 17.
16.3% at twenty-eight and thirty-two years.

*No. of Pregnancy (177 Cases).*

| | | | | | |

14.4% 101 or over.

*Fetus (210 Cases).*

Found in 24.2%.
In tube in 30% of 51 cases.
In abdomen in 20.2%.

*Diseases of Tubes and Ovaries (202 Cases).*

16.7% opposite tube diseased.
34.6% adhesions found.
15.3% cystic ovary.
19 cystic ovary opposite side.
12 cystic ovary same side.
4 both ovaries cystic.

CONCLUSIONS.

1. Irregular flowing seems to play the important part given it in the books as a symptom of extra-uterine pregnancy.

2. The importance of a long period of sterility as a cause of extra-uterine pregnancy does not seem to be borne out by these statistics.

3. Conditions possibly leading to extra-uterine

pregnancy: The fact that cystic ovaries, disease of the opposite tube, adhesions or a previous miscarriage occurred in over 83% of 202 cases is suggestive, and is in agreement with authorities as to the possible relation of such conditions to extra-uterine pregnancy.

4. The fact that in only 26.5% of 207 cases the pain was sudden is of interest. In about three fourths of the cases the sudden, severe pain was preceded by pain of less severity, coming on gradually.

5. Of considerable interest is the leucocytosis observed in the cases in shock. This is apparently a perfect example of leucocytosis after hemorrhage. The finding of a temperature of 100 or over in 43.4% of the cases, and of a temperature of 101 or over in 14.4% of cases, is also of interest. Ordinarily it is supposed these cases rarely have any fever.

6. Active hemorrhage at operation. Some observers with much experience in this subject say that active hemorrhage actually seen at operation occurs so rarely as to be practically negligible. It occurred in 4.4% of all the cases operated on. It is possible that the hemorrhage was in some cases started up by operative manipulation.

7. Immediate *vs.* delayed operation. It is with misgivings that one approaches any definite conclusions in regard to this subject. Many operators of great experience differ about the best procedure. I must conclude that they are not greatly influenced by statistics and that in this condition every case must be judged on its own merits. These statistics show that it is best to wait for a time before operating on the cases in shock. Twenty-five per cent mortality of those operated on in shock, 8.3% mortality of those for whom the operation was delayed for a time. Active stimulation and blood-pressure-raising drugs seem to be best given after the bleeding points in the tube are secured. Rest and morphia while waiting are most important. Waiting any length of time with a case of extra-uterine pregnancy in good condition is dangerous, since it has been shown that bleeding may recur at any time, so that in a few hours the patient may be again in a desperate condition.

## Clinical Department.

### TWO CASES OF ABDOMINAL PREGNANCY, ONE AT TERM.*

BY EDWARD REYNOLDS, M.D., BOSTON.

Private Case Records 2382. Seen March 6, 1905, with Dr. Lawrence, of Malden, who had himself been called in consultation by her physician a few hours earlier. She was thirty years old and supposed to be within a few days of term in her second pregnancy. She had had "fainting spells" early in this pregnancy, had had pain and flowing, and had been curetted, little material obtained. Between that time and the time I saw her she had had four sharp collapses, treated by rest in bed. The last and most severe collapse occurred on March 4, two days before my visit. She was said to have gradually improved during that time, but had a feeble pulse of 140, was blanched and looked as though it were very questionable whether she would survive. The abdomen was very prominent, with marked frog belly, and a tumor easily outlined by the eye in the lower abdomen, lying with its long diameter transverse and extending from the pubes to about three inches above the umbilicus. The abdominal wall was very thin and, of course, very flaccid. The outlines of the distended intestinal coils were visible to the eye in the upper abdomen, while in the lower and more prominent portion the outline of a child was distinctly suggested by inspection. The upper abdomen was tympanitic, the lower flat. The fetal members of a large child were distinctly perceptible to the touch, apparently immediately beneath the thin abdominal wall, and following the visible outlines. No fetal heart was heard, but the so-called placental soufflé was loud immediately above the pubes and over the lower half of the space occupied by the child. No active movement of the fetus could be provoked even on free passive movements of its limbs. On vaginal examination the cervix was patulous, admitting the finger readily, and apparently well into the body of a slightly enlarged uterus with velvety mucous membrane. Diagnosis, abdominal pregnancy with child probably recently dead. The condition of the patient entirely precluded any thought of immediate operation. The shock of even a slight operation would undoubtedly have proved fatal. Even had this not been so, I think that it would have been wise to wait ten days or a fortnight for the subsidence of the placental circulation. She reacted very slowly from her collapse and was not thought to be in condition for removal to the hospital, or for operation, until March 22d, more than two weeks after I saw her. She was then sent in and I operated on the 24th. Her pulse was then between 110 and 120, and of fair strength. Temperature normal, color very pale, but condition on the whole fairly good under the circumstances.

A small exploratory incision was made in the median line just below the umbilicus, or at about the middle of the gestation tumor, in order to permit its enlargement upwards or downwards as the conditions might suggest. The great omentum presented, its vessels greatly engorged and its whole substance of a brilliant green color, resembling that of meconium. There were no adhesions between the surface of the omentum and the anterior wall, but its edge was firmly adherent around the whole circumference of the brim of the pelvis, completely covering in the gestation tumor, and walling it off from the upper cavity of the abdomen. The wound was enlarged downward almost to the pubes and the upper abdomen walled off by gauze placed between the abdominal wall and the omentum just above the upper end of the incision. The edge of the omentum was so firmly adherent that it could not easily have been separated from the pelvic brim, but it was very easily split with the fingers in the median line of the abdomen, disclosing the fetal surface of the placenta, which was subsequently found to have been attached to the intestines behind it, but had been centrally separated from them by an enormous mass of blood clot which had dissected the placenta free almost to its edges, bulging it upward into the abdomen above the child, which had evidently been displaced downwards thereby. The placenta was gray and friable. It was easily torn through, was separated without especial difficulty along its edges, practically by tearing its substance along the edge, and was removed with the greater part of the blood clot. The fetus followed, large and in an advanced stage of aseptic

* Read before the Obstetrical Society of Boston, Oct. 25, 1910.

decomposition. The cavity of the pelvis was still filled with old blood clot so thoroughly organized and so intimately adherent to the uterus and coils of the intestine that it was thought unwise to attempt to remove it. The cavity which had been occupied by the fetus and placenta was now packed with gauze, which was brought out through the wounds in the omentum and abdominal wall. The field of operation was thoroughly cleaned, the gauze packing in front of the omentum which walled off the upper abdomen was removed and replaced by clean gauze, and this was brought out through the upper end of the abdominal wound. Fifteen large strips were used in these two packings and the entire wound was thus filled with gauze, no suture being attempted. Like most surgeons nowadays, I am far from fond of open wounds or gauze, but the conditions in this case seemed to preclude any other method.

The patient was put back to bed in very fair condition, and rallied well from the primary shock. She was, however, in very feeble condition for several days, requiring constant stimulation, including repeated salt solution under the breast. On the third day she was distinctly reacting, and from that time did well. The gauze in the gestation sac was removed strip by strip at intervals, as the patient's strength permitted, the last six pieces being removed together under nitrous oxide on the tenth day. The remaining gauze, that which walled off the general cavity, was by this time extremely adherent and was removed very slowly, though pulled at daily, the last being extracted about six weeks after operation. It may be that it would have been wiser to have removed this gauze earlier, but during the first two weeks after operation each removal of gauze was followed by so much prostration that it was necessary to proceed with great caution and the discharge from the gestation sac was so profuse and foul that I was unwilling to risk an early removal of the upper gauze.

The patient was able to go to the western part of the state about ten weeks after operation, and then did uninterruptedly well, writing to me at intervals for a year or more to assure me of her entire health.

Private Case Records 2708. Seen by me March 15, 1907, with Dr. W. J. Macdonald, of Chelsea; thirty-six years old. Married twenty-one years. Two children eighteen and nineteen years old. One miscarriage two years before this date. Catamenia regular in June, 1906; none in July. August catamenia profuse, requiring packing, supposed to have miscarried. Catamenia regular in September and October. None in November. Dribbled from Dec. 15 to about Jan. 15, when she had an attack of moderate abdominal pain lasting some hours, such attacks occurring about once a week during the next month, when one of them was followed by a "faint"; since then weekly attacks of pain but without fainting.

On examination, the lower abdomen was occupied by a soft mass of irregular outline, extending nearly to the umbilicus and crowding the vaginal vault downward. I thought that I could make out a uterus of about normal size lying below and in front of it. Diagnosis, "Question between a soft neoplasm, or an extra-uterine, with inflammatory disease a bad third."

On paper the diagnosis of advanced extra-uterine would seem plain, but every surgeon knows the difficulties inherent in this diagnosis in the absence of perceptible fetal members, and I make no apologies for the state of doubt shown by the above entry in my records.

She had been in bed many weeks and was in poor but by no means inoperable condition. She entered my private hospital and on March 18 I opened her abdomen. A blood clot was seen immediately beneath the abdominal incision and there was a considerable amount of free blood and clots in the lower portion of the abdominal cavity. On removing this a tumor presented. It was covered by peritoneum and looked not unlike the wall of a distended uterus. Its upper portion was covered by coils of adherent small intestine, which on closer examination proved to be connected with the tumor by a gray necrotic-looking exudate nearly half an inch thick.

The general cavity was walled off with gauze, and the fingers were readily passed through the necrotic tissue below the intestine, separating them from the tumor, which was now seen to be evidently the gestation sac of an abdominal pregnancy. It was opened by tearing, the cord presenting immediately through the rip. With this as a guide a fetus about ten inches long and lying amid broken-down clots was easily found and removed. The placenta was adherent to the bottom and right side of the pelvis and to the entire mesentery of the small intestine. It seemed very firmly attached and there was so much necrotic material visible that further trauma seemed unwise, more especially as there was already fairly free oozing from the bottom of the cavity. The cord was cut off close to the placenta and the gestation cavity packed with seven strips of gauze, hemorrhage being apparently well controlled. The toilet of the peritoneum was made, the walling-off gauze above the gestation sac was removed and replaced by fresh gauze. Three provisional sutures were inserted in the abdominal wall. Patient removed from table in fair condition.

The history of this case suggested that pregnancy had persisted for nine months. The size of the child was that of a six months' fetus. I am unable to offer any opinion of value upon whether it had been carried in the abdomen for some months after its death, or whether the history was misleading as to the length of pregnancy.

During the first two days the pulse ranged from 130 to 150, the wound oozed very freely, the patient became extremely thirsty and vomiting was persistent. Small quantities of salt solution were given by the rectum, stypticin was used without effect. On the third day the oozing was distinctly decreasing, but thirst and vomiting were distressing and salt solution was used more freely. From this time on she steadily gained in condition, the first gauze was removed on the fifth day, and the last gauze from the gestation sac was removed on the eighth under nitrous oxide. The gestation sac was irrigated daily with sterile water. The remaining walling-off gauze was pulled upon daily, and the last piece was removed on the twentieth day. Placental tissue, membranes and organized blood clot were washed out in small fragments daily.

On the forty-fourth day a piece of placenta two inches long and an inch wide floated out of the wound during irrigation. This was followed by a single temperature of 102, the next temperature being normal. The patient went home at the end of seven weeks. A sinus persisted for about four weeks later, when it closed spontaneously. She was seen several times during the next year, always in excellent condition.

Both these cases were seen after the death of the fetus, and both were operated upon after necrosis of the placenta was well established; they consequently illustrate only one phase of this subject. Both were operated upon by the same method, i. e., walling off the general cavity, opening of the gestation sac by careful dissection with the fingers, removal of the fetus and of such portion of the secundines as could be readily

separated, and packing of the gestation sac with gauze.

I think that the keynote to success in such cases rests in selecting for the time of operation a date long enough after the death of the fetus to permit the practical cessation of the utero-placental circulation, but before the patient begins to show the cachexia which must necessarily attend the absorption of so large an amount of necrotic material. I would place it in the second or third week after the death of the fetus, the choice within these limits being determined by the progress of the patient's condition.

I think further that the essential technical points are a wide incision, thorough walling off of the general cavity if this has not already been effected by nature, great care in ascertaining the position of the intestines before the gestation sac is torn into, and avoidance of any attempts at forcible removal of the placenta. It is fortunately possible to take plenty of time to study out the relations between the gestation sac and the intestine, as the rest of the operation occupies almost no time at all, and any reasonable amount of time so spent is most wisely used.

## REPORT OF A CASE OF FULL-TERM INTRA-ABDOMINAL PREGNANCY.

BY JOHN W. LANE, M.D., BOSTON,
*Third Assistant Visiting Surgeon, Boston City Hospital.*

Patient, Mrs. M. H., thirty years.

*Past history.* — Married seven years ago; five years ago had a miscarriage at four and one-half months induced by a fall down stairs. Past history otherwise negative, patient always having been well up to the beginning of the present pregnancy.

*Present history.* — Sometime in March, 1910, patient began to have morning vomiting and nausea, which soon became almost pernicious in character and occurred almost any time through the day. This excessive vomiting, which persisted during the early months of pregnancy, was the cause of marked loss of strength in the patient and entailed also a drop in weight from 175 to 125 lb. The pregnancy ran in about the following fashion: During the whole period there was very obstinate constipation relieved only by 30–40 gr. of cascara or by compound enemata. In June and July there were weekly attacks of very sharp abdominal pain in the left side below the kidney. These attacks required ¼–½ gr. of morphia subcutaneously for relief. In the latter part of July, fetal movements were felt by the mother, and from that time were the cause of much suffering to her.

From March to the middle of June there was almost constant metrorrhagia. Then without any noticeable symptoms, the flowing ceased and did not recur. During the last month of the pregnancy the patient complained of frequent and somewhat painful micturition. There was evidence of a slight degree of cystitis. There was a slight trace of albumin in the urine. There was no headache. The patient at times was slightly disturbed mentally, being childish in action and irrational in speech.

On Nov. 4, 1910, sharp pains in the back simulating labor pains began and recurred at ten-minute intervals. These pains were associated with marked rigidity of the anterior muscles and pain over the pubes and sacrum.

Examination at this time by her physician, Dr. Thomas J. Coyne, of Roxbury, to whom I am indebted for the privilege of operating upon this patient and reporting the case, showed the abdomen uniformly enlarged and the fetal parts palpable, the breech being high and to the left. Fetal heart 144, audible at a point 1½ inches above and 1 inch to the left of the umbilicus. Vaginal examination showed a large boggy tumor filling the posterior cul-de-sac. The cervix was slightly soft, not dilated, and pointed to the os pubis, lying directly behind it.

On account of the debilitated condition of the patient it was suggested to her by Dr. Coyne that a rapid Cæsarean section would give her and the baby a better chance than a prolonged labor. The patient and her husband readily assented and the operation was performed at 9.20 P.M. It can honestly be stated that no suspicion of the condition found had been entertained.

*Operation.* — Median incision about 8 inches carried to the left of the umbilicus. The tissues in the linea alba were boggy and edematous, rather "porky" in appearance. As progress to the peritoneum was being made it was opened in the region just below the umbilicus and immediately there was a gush of dark coffee-colored fluid. The wound was rapidly enlarged in either direction and at once the free breech presented in the wound, the back of the fetus pointing to the mother's left side. The baby was pulled through the wound and delivered. The cord was clamped and cut. Immediately on delivery of the baby there ensued from the abdomen a most frightful hemorrhage. Rapid search for the placenta showed it to be situated in a large saccular cavity in the left lumbar fossa anterior to the kidney, and there was very free bleeding, the placenta having apparently been partially detached on delivery of the baby.

The placenta was separated from its site with great difficulty, being very adherent, and the sac packed full of gauze to control hemorrhage temporarily. The uterus was now sought for and found to be apparently normal save for its being enlarged to the size of a 2½ months' pregnancy. Inspection showed the tubes and ovaries apparently normal in appearance. No trace of rupture of tube, uterus or ovary was visible. The sac was now pulled out of the wound as far as possible and found to be adherent to the anterior abdominal wall in front, the great omentum above and to the descending mesocolon.

The packing was now rapidly removed and four large sinuses in the placental site, which was at the descending mesocolon, were clamped and tied. Attempts at further ligation were now stopped on account of the patient's condition, which had become alarming. The sac was packed with gauze and the abdominal wound closed with through-and-through silkworm gut sutures, with a drain just below the umbilicus. Patient was actively stimulated with strychnia and salt solution and adrenalin 1-50,000 under the breast and continuous saline by rectum.

Artificial respiration was necessary for the baby, also mouth-to-mouth insufflation, and in twenty minutes the baby was crying lustily. It was a boy about 8½ months. Twenty-four hours after delivery the baby having become cyanosed died suddenly.

Nov. 7, 1910: Under ether the packing was removed. On removal there escaped a large amount of dark blood. At midnight of the same day the patient's condition again became critical. The pulse was 140, respiration 50; there was marked pallor and air hunger. With the husband acting as the donor, an arterial transfusion was done, the blood being allowed to run for twenty-five minutes, at the end of which time the

patient's color was markedly improved and the husband began to sigh deeply.

After the transfusion the pulse dropped to 108 and her condition showed marked improvement. After this the patient did fairly well until Nov. 14, when she complained of abdominal pain and tenderness and ran a temperature of 102.5. Examination showed the lower abdomen distended, tender and indurated. Ether was given and the lower angle of the wound opened and about a quart of bloody pus evacuated.

On Nov. 19 she began to complain of very severe rectal pain, spasmodic in character, associated with a constant desire to stool. A compound enema gave no relief from the pain, although there was some fecal matter removed. Rectal examination showed a very large mass of inspissated fecal matter extending as high as could be reached. This was broken up and enemata gave results with complete relief. From this time on convalescence was rapid and patient left the Boothby Hospital on Nov. 23, in good condition save for a discharging sinus at the lower angle of the wound.

There are certain features connected with this very unusual case which are deserving of comment. In the first place, if we exclude rupture of the tube, uterus or ovary by the macroscopic appearance we have a case of true intra-abdominal pregnancy, a condition which Whitridge Williams, of Johns Hopkins University, says has probably never authentically existed.

Personally I feel that in the absence of any adhesion of the sac in which the fetus developed to the uterus, tube or ovary there is proof exclusive that no rupture of them occurred and that impregnation began and finished in the abdominal cavity. I maintain that if this pregnancy had been either tubal, ovarian or uterine primarily and terminated as in this case there would in all likelihood have been some attachment of the sac to some of these organs. In this particular case no such condition existed. Another point of interest which arises is in regard to the treatment of the sac and placenta. Most writers in speaking of this condition state that the sac should be sutured to the wound and the placenta allowed to remain and slough gradually. The obvious purpose of this treatment is to avoid hemorrhage which ensues on detachment of the placenta, there being no muscular contraction to close the bleeding sinuses. This was not done because, on delivery of the fetus, the placenta had become partially detached and it was decided to get it out as speedily as possible.

I think the best method of procedure in these cases will always be more or less a matter of conjecture; because of their great rarity the best form of treatment will always be open to discussion. Another point which I desire to emphasize is the wonderful improvement which followed the transfusion of blood, scoring, I think, another triumph for that operation.

---

AT a meeting of the Philadelphia College of Physicians, April 5, portraits were presented to the college of the late Dr. George Couvier Harland and Dr. James Tyson. Both portraits were accepted by Dr. George E. de Schweinitz, president of the college. — *Jour. Am. Med. Asso.*

## Medical Progress.

### PROGRESS IN PHARMACOLOGY AND EXPERIMENTAL THERAPEUTICS.

BY MAURICE VEJUX TYRODE, M.D.

#### PHARMACOLOGIC AND OTHER AGENTS IN THE THERAPEUTICS OF GASTRO-INTESTINAL AFFECTIONS.

*Effect of certain agents on gastric hyperacidity and gastric mucus.* — ACCORDING to the work of Bolton, extreme hyperacidity may cause gastric ulcers, and there is no doubt concerning the irritant effect of HCl even in diminished quantity on an irritated or ulcerated gastric or duodenal mucosa. Kaufman, Aldor, Schalij and more recently Chenisse have found a deficiency in gastric mucus in hyperchlorhydria and ulcers and assume that symptoms of hyperacidity are rather due to lack of protective mucus than to the increase in HCl alone. Schalij reported some cases in which the symptoms were those of hyperacidity, but one hour after the test meal the acidity was not above normal, while the lack of protecting mucus explained the disturbance. He found that oil seemed to replace the missing mucus and to afford protection to the gastric mucosa, but this had to be given before meals. Kaufman found that silver nitrate stimulated the production of mucus and thus helped in the relief of the condition. Chenisse agrees with these authors that the absence of mucus is a most important factor in the production of the symptoms of hyperacidity, but he recommends the use of gelatine instead of oil to replace the mucus. He also stated that the benefit obtained from bismuth is probably due to its stimulating action on the secretion of mucus and supports this opinion by citing the experimental research of Dubus, who showed that bismuth not only increases the secretion of mucus, but also causes the latter to adhere better to the stomach walls. Surmount and Dubus experimented with different salts of bismuth and found that the carbonate and oxide are very inferior to the subnitrate in stimulating the secretion of mucus, yet they believe that these are of some value in hyperacid conditions on account of the basic nature of these salts.

*Hydrogen peroxide.* — It was first demonstrated by Petri, afterwards by Goodman, that hydrogen peroxide had marked effect in attenuating symptoms of hyperacidity, and these authors also showed experimentally a decrease in the HCl in the stomach. More recently Poly performed an experimental research in which he found that hydrogen peroxide produced a decided increase in the quantity of the gastric mucus. In one dog he was able to show after the usual test breakfast an increase from 0.35 up to 0.65 gm. In the cases in which he experimented and in which the animals were killed there could not be demonstrated any special changes in the glandular apparatus of the mucous membrane when the concentration was up to 2%. The author terminates by warmly recommending this agent in the treatment of hyperacidity. He himself

administers it either in the form of hydrogen peroxide in the milk of almonds or as the tablets of magnesium-perhydrol (Merck). These results with hydrogen peroxide concerning its effect on gastric mucus are exceedingly interesting in confirming the works of authors cited above.

*Atropine in gastric diseases.* — Some members of the solanaceæ family containing the tropines, as hyoscyamus and belladonna or their alkaloids, especially atropine, have been used and recommended in the treatment of gastric ulcer by various authors, including Block, Bowers, Mathien, Von Tabora and Schick. Von Tabora was one of the first to accentuate the use of atropine subcutaneously and to lay great stress upon its scientific mode of action in gastric ulcer, i. e., by decreasing the secretion of HCl and relaxing the spasm of the pylorus. Schick more recently made a rather exhaustive study of the action of atropine in obstinate cases of gastric ulcer. His experiences were similar to those of Von Tabora, and he believed that his good results came from the relaxed musculature of the stomach and pylorus and decreased gastric secretion. He had some cases where all previous methods of treatment had failed and where surgery seemed to be the only recourse. His method is to inject subcutaneously twice daily from 0.001 up to 0.0015 gm. atropine-sulphate morning and evening for a period of from four to ten weeks while the patient is on a milk-cream diet. The subjective symptoms usually disappear immediately, and this is probably to be ascribed to the paralysis of the vagus terminations in the stomach, since vagus irritability is very frequent in gastric ulcer and is probably a rather important factor in the condition.

This beneficial effect of atropine helps to substantiate the views of Mayo and others on reflex pylorospasm from ulcer or distant affections as chronic appendicitis. It is conceivable that an ulcer in the form of a fissure as observed frequently by Codman would be beneficially influenced by relaxation of the sphincter by atropine or other means, just as relaxation helps fissure in ano. It is probably because this result is obtained in gastro-enterostomy that this operation may give such remarkable results even without any other operative procedures, the *modus operandi* being drainage of the irritating fluid through a new opening, thus preventing reflex spasm caused by the passage of irritant material over an ulcerated surface.

Waldvogel has also used atropine in doses of 0.0005 gm. with most excellent results in conditions which he calls gastrospasm. He takes rather a conservative view and considers gastrospasm chiefly as a neurosis independent of organic diseases of the stomach, but generally associated with an excess of HCl. He considers this affection represents over half of all the gastric diseases. The reviewer does not agree with him in this respect.

*Serotherapy of gastric and duodenal ulcers.* — Bolton has been able to produce gastric ulcers experimentally by the use of gastrolytic sera, but failed when the normal HCl of the gastric juice was neutralized by alkalies. This led to the assumption that two factors are essential for the presence and propagation of ulcers, i. e., besides the presence of HCl, a decreased antipeptic power of the organism, and from these facts has been evolved the use of antipeptic and antitryptic sera.

Hort made a study of over a score of duodenal ulcers treated with horse-serum having antipeptic and antitryptic activities. Most of these cases had resisted all other forms of treatment, yet out of 24, 21 were apparently cured. The relief of pain, hemorrhage, hyperacidity and other dyspeptic symptoms was a most striking feature in all cases. Besides the use of serum, Hort lays great stress upon the beneficial effects of proteid increase in the diet, believing that these foodstuffs increase the resistant power of the body against the cause of the disease, besides assisting in the local repair, and in taking up the excess of peptic and tryptic molecules, while the serum strengthens the living cells of the body against the action of these.

Mayhew, who tried Hort's treatment on a number of cases, reports most successful results, a striking feature being early relief from pain. This was true in all cases, although he allowed a generous diet, much earlier than is usually possible. The anemia improved rapidly. The nausea and vomiting stopped earlier than under any other form of treatment, while the nutrition of the patient was also better. He insists that besides the horse-serum, of which he gives 10 ccm. three to four times per day in ½ oz. water immediately after meals, the following are also essential factors: (1) Absolute rest in bed for two to three weeks. (2) No drugs except a simple purgative. (3) Diet is dry throughout: no milk, soup or fish. Meals may be given every two hours, consisting in rotation of stale bread, yolks of lightly cooked eggs, white meat of chicken. Only liquid allowed is 10 oz. of hot water at 7 A.M., 11 A.M. and 1 P.M. The dietary is doubled in five days and on the seventh or eighth day pounded meat lightly cooked may be added. By the end of the second week meat forms the chief article of diet and soon a return to full diet is gained, but alcohol, soup, tea, coffee and all starchy puddlings are forbidden for six months.

Herschell, of London, is also a strong believer in the good effect of horse-serum, and this forms an important feature in his treatment of duodenal ulcer. He uses it not only during the active stages of ulceration, but also afterwards to prevent recurrences. His prophylactic method is the following: One dose after the principal meal, once daily for one month, then twice a week for another month. Afterwards in the spring and autumn he gives for one month a dose of serum twice a week.

*Mineral waters in gastric secretion.* — Formerly it was universally taught that alkalies always increased the gastric secretion, because the alkaline saliva was a natural stimulant to this secretion. We know now that the importance of the

saliva as a gastric stimulant has been much overrated, and, in fact, experimental data has been brought out to show that alkalies may not only neutralize but decrease the secretion of HCl in the stomach. Since in mineral waters used for therapeutic purposes the presence of alkalies is usually complicated by that of various neutral salts, it is thus very interesting to note the researches of Theohari and Babes. According to their work, which was on dogs with a Pawlow's fistula, the gastric secretion is much influenced by different mineral waters, the various elements being influenced in different ways. The water of one of the springs tested contained 9.7 gm. of sodium chloride and 9.7 gm. of sodium bicarbonate, and this water invariably checked the gastric secretion. Water from another spring with 13.2 gm. of the chloride and only 6.9 gm. of sodium bicarbonate stimulated the secretion, increasing it by 107% in some of the tests. The average increase was from 40 to 80%.

This corroborates the view generally held that for diseases of the stomach with a decrease of HCl, such waters as those of Kissingen and Homburg, which contain a rather higher proportion of sodium chloride, are more appropriate, while for those cases with increased acidity, such waters as those of Carlsbad and Marienbad, containing a lower proportion of sodium chloride, but being richer in sodium bicarbonate, are better suited.

*Caffeine on the gastro-intestinal tract.* — Salant, after a long investigation on caffeine, has found that doses insufficient to produce immediate symptoms are able to cause marked chronic intoxication in rabbits, dogs and cats. The poisoning consists of marked effect on the nutrition of the animals, loss of flesh and strength, frequently terminating in death. The changes found at autopsy showed inflammation and ulceration of the gastro-intestinal tract, but especially of the stomach. These results were obtained as well by subcutaneous as by internal administration. It may be remarked in this connection that diarrhea and intestinal putrefaction were frequently symptoms, especially in dogs. Finally, experiments were also made on rabbits to ascertain the effect of starvation. When starved four to five days the resistance to caffeine was markedly diminished, the fatal dose being about 30% less than in well-fed rabbits.

These results are exceedingly interesting and substantiate the reviewer's idea that both tea and coffee are very undesirable in all forms of gastro-enteric disease, on account of the local irritant effect besides the action on the nervous system.

*Phenol and the gastro-intestinal tract.* — Sollman, Hanslich and Pilcher performed a research with a view of studying the absorption of phenol in the gastro-intestinal tract and have come to some very interesting conclusions as follows: (1) When phenol is placed in the alimentary canal, the absorption at first is very rapid, but is quickly checked and soon practically arrested. (2) When phenol is placed in the stomach, only traces pass into the intestine; a large proportion could be recovered by gastric lavage. (3) The check of the absorption coincides in time with the development of toxic, systemic effects of phenol. The authors believe and show experimental evidence to support the fact that this action of phenol is not due to corrosion of the bowels, but rather to a specific effect.

These results are very valuable in teaching us the scientific method of treatment for phenol poisoning. On theoretical grounds both gastric lavage and purgation are distinctly indicated. It is interesting to note in their experiments the protective mechanism of nature in that absorption begins to diminish as soon as toxic symptoms arise.

*Thymol in enteritis.* — Cade and Garin observed a series of patients between twenty-five and forty years of age with variable syndromes, but in most cases having some diarrhea and invisible hemorrhages persisting for some months and years. In some cases periods of constipation intervened and in some the tenesmus and colics simulated dysentery, or the false membranes in the stools suggested mucomembranous colitis. Almost all the patients were neurasthenics, and many showed predominant gastric symptoms. They uniformly found in all the cases of this series eggs of the tricocephalus dispar and occult blood in the stools, from which they made the diagnosis that the enteritis was due to the above-named parasite. They gave thymol in 15-gr. doses three to four times a day for three to four days, following with a saline purgative, the patient abstaining in the meantime from alcoholics and oil. This course was repeated after an interval of a few days. It did not always remove all the worms even with several courses, but always produced great improvement in the patient's condition and never any untoward effects.

Raillet, having found worms in the appendices of infants, resolved to try the effect of thymol in children having appendicitis. He gave thymol for several days before the operation, but the worms when found in the appendix were never killed by the thymol. This shows that drugs can have no influence within the blind appendix.

*Intestinal poisons in arteriosclerosis.* — Metchnikoff continued his studies on the influence of certain intestinal poisons on arteriosclerosis, i. e., the phenyl-sulphate of potassium and paracresol. He finds that these substances have very little immediate toxic effect even in large doses, but the prolonged ingestion of small doses produces well-marked atheromatous changes and also lesions of hepatic cirrhosis. One monkey who had received paracresol for two months in small doses, at post-mortem section showed marked cerebral and renal arteriosclerosis, besides liver changes named above. Metchnikoff believes that in this series are to be found a cause of physiologic (?) arteriosclerosis. To prevent this he recommends a mixed diet in preference to a purely vegetarian régime. He also believes that these putrefactive changes may be checked by the employment of lactic-acid bacteria.

*Antiseptic action in the stomach.* — Collodi, after an extensive research, comes to the conclusion that the bactericidal power of the gastric juice is due principally but not exclusively to HCl. He has also shown that neutralized gastric juice has a definite antiseptic action, but probably not sufficient to protect individuals from intestinal infections in all cases. The antiseptic action is tremendously influenced by the character of the diet. It is most marked with meat, less so with milk, still less with starchy foods, very slight with fats and almost absent with water. He finds also that pleasant food increases the antiseptic action in parallel lines with the secretion.

*Nicotine on gastric secretion.* — Skaller made experiments on dogs with tobacco smoke dissolved in water and injected into the circulation and he found marked increase in the gastric secretion when the cigar smoke contained nicotine, but not if it was free from nicotine. He feels no hesitancy in saying that the products of combustion in tobacco smoke are harmful to the stomach, yet the chief noxious agent is nicotine. His experiments well explain the gastritides, the hypersecretions and hyperacidities frequently seen in excessive smokers. He has named the disease "nicotine hypersecretion."

*Pantopon and gastric secretion.* — Rodari's experiment on dogs with Pawlow's fistulas have shown that pantopon (the mixture of opium alkaloids) causes a marked increase in the gastric secretion, but, as has been shown before for morphine, it decreases the motility. According to this research pantopon seems to the reviewer a most undesirable drug when symptoms of hypersecretion are present.

*Cykloform in gastro-intestinal affections.* — Wyss made experiments and clinical tests with cykloform, a local anesthetic practically insoluble in water of the type of anesthesin and orthoform. He found its toxicity very low, 1 gm. of cykloform producing no toxic effect whatever on a cat, while its local anesthetic action is exceedingly powerful. He recommends it internally in gastralgia in doses of 0.2 to 0.5 gm. several times daily. In such conditions, and also in vomiting of pregnancy, he obtained remarkably good results. He has used it with success and recommends it in painful affections of the anus and rectum in the form of 20% ointment or suppository.

## Book Reviews.

*Makers of Man.* A Study of Human Initiative. By CHARLES J. WHITBY, M.D. (Cantab.). With forty-seven half-tone and other plates. New York: Rebman Company. 1910.

This philosophic treatise by a physician presents the author's experiments in the psychologic elucidation of genius, based on analysis of the careers of "forty world-famous individuals," whom he divides, according to their temperaments, into four groups,— the practical, the esthetic, the intellectual and the ethico-religious. The main result of this inquiry he considers to be the "demonstration of the predominance of a supermechanical, super-physiological spontaneity in the determination of human careers." Accordingly he believes that the genius of the future will fit less and less satisfactorily into this classification, but will tend to become a combination of all four categories, a sort of *Uebermensch*. To Dr. Whitby the lives of great men all "show that unity of manifestation which we expect from the exfoliation of a self-determining spontaneity." To those of us to whom such lives had not hitherto afforded this expectation so vividly as the reminder that "we can make our lives sublime," the doctor's studies furnish material for very profitable reflections in the interpretation of character. Especially interesting, in the chapter on "Power in the Crucible," is his psychologic analysis of the relations of woman to man and superman.

*A Treatise on Diseases of the Eye.* By JOHN E. WEEKS, M.D., Professor of Ophthalmology in the University and Bellevue Hospital Medical College, New York. In one octavo volume of 944 pages, with 528 illustrations and 25 full-page plates. Philadelphia and New York: Lea & Febiger. 1910.

This treatise is really a condensed encyclopedia of ophthalmology; everything that is valuable and important is included. The author with great industry has collected his material and selected it with skill and has succeeded in impressing his own mind on the work, so that the book is not a mere compilation. The best work of former years is included as well as the most recent progress. The illustrations are numerous (528) with many colored plates, including a full-page one of the trachoma bodies of Halberstädter and Prowazek. The embryology and anatomy of the eye are treated comprehensively in the first part of the book. An excellent chapter on the relation of diseases of the throat, nose and accessory sinuses to the eye is given. The chapter on operations is valuable, especially the part on plastic operations on the lids. The book will prove as useful to the specialist as to the general practitioner, and in printing, paper and general arrangement leaves nothing to be desired.

*Introduction to the Analysis of Drugs and Medicines.* By BURT E. NELSON. New York: John Wiley & Sons. 1910.

Nelson's book fills a decided need, for with the present more extensive drug analysis carried on by government, state and municipal health boards and private individuals, some small work with tangible facts and methods such as this is exceedingly valuable. The author gives both the chemical and microscopic methods of recognizing drugs and chemicals. A most valuable addition to this excellent work is a table of chemical compounds used in medicine, arranged according to melting point, boiling point and carbon contents. Any one who has wearily searched for an unknown body in a mixture will appreciate these tables.

*The Surgery of Childhood.* Including Orthopedic Surgery. By DEFOREST WILLARD, A.M., M.D. (Univ. of Penn.), Ph.D., Professor of Orthopedic Surgery, University of Pennsylvania; Surgeon (twenty-six years) to the Presbyterian Hospital; Surgeon-in-Chief, Widener Industrial School for Crippled Children; Ex-President American Surgical Association, American Orthopedic Association, Philadelphia Academy of Surgery; Ex-Chairman Surgical Section, American Medical Association; Fellow Philadelphia College of Physicians, etc. With 712 illustrations, including 17 in colors. Philadelphia and London: J. B. Lippincott Company.

Willard's handsome volume of 800 pages is extremely worth while and is an important addition to our knowledge of the subject of surgery of children. It is elaborate, it is inclusive, and it makes clear to the reader the notable distinction which exists between the surgery and surgical anatomy of children and the corresponding surgery of adults. As the author says, "It is exceedingly important that the pediatric surgeon should acquaint himself with the anatomy of the child. The teaching in this respect is usually very imperfect, since routine dissections are usually made upon adults, and the ordinary graduate has no knowledge whatever of children's anatomy. The exceeding smallness of the organs and tissues will be a surprise to one who has not dissected infants and small children. The extremely narrow diameter of the trachea, for instance, readily accounts for the great interference to respiration as seen in laryngeal diphtheria." In his opening paragraph he remarks further upon the well-known truth that "surgery of childhood differs in many respects from surgery of adult life, and requires special consideration both by the general surgeon and the family physician. The pediatric surgeon must necessarily depend largely upon objective symptoms for his conclusions; consequently he must possess a high degree of acute observation, intelligence and discrimination in arriving at a diagnosis and in supervising the treatment."

The author takes up in their order all of the important surgical subjects as applied to the child. He insists upon the need of a broad general knowledge of disease and the importance of close co-operation between the internist, the surgeon and the more narrow specialists. Many surgeons have seemed to think that the special interest in children's diseases is extremely limited, and concerns itself with such conditions as epiphyseal fractures, congenital malformations and abnormalities such as hydrocephalus, spina bifida, etc., and with unusual internal derangements such as infantile stenosis of the pylorus. In fact, these conditions are but special instances of the very wide difference which exists between the disease processes found everywhere throughout the body in childhood on the one hand, and in adult life on the other.

The book is anything but a treatise on orthopedic surgery, though, indeed, the author does devote several chapters to orthopedic surgery proper, and extremely important chapters they are. In this connection one may wish he had said something more definite regarding the malformations and displacements of the digestive organs, conditions which are now recognized as playing an important part in the healthy development of children, since they directly influence disease processes in other parts of the body.

While the writing is somewhat disjointed and fragmentary in places, the book holds well together as a whole. It is interesting and will be an important addition to the library of the general surgeon as well as of the pediatric surgeon.

*The Cœliac Axis.* By PIERRE DESCOMPS. Paris: G. Steinheil. 1910.

This painstaking French work is the first of a series projected by the author on his researches in the surgical anatomy of the abdominal arteries. The book is extremely thorough and lucid and is beautifully illustrated. It would seem, however, to be of less practical value to the surgeon than to the anatomist interested in the study of arterial variations.

*Anemia.* By DR. P. EHRLICH and DR. A. LAZARUS. Part I. Vol. I. Normal and Pathological Histology of the Blood. Second edition (enlarged and to a great extent rewritten). By DR. A. LAZARUS and DR. O. NAEGELI. Translated from the German by H. W. ARMIT, M.R.C.S., L.R.C.P. (London). With 5 illustrations in the text and 5 colored plates. New York: Rebman Company. 1910.

This first volume of the second edition of Ehrlich's standard book on the blood, prepared for publication by two of his pupils, is of particular interest at this time when the author has become so conspicuous for his work on atoxyl and other arsenic derivatives in the treatment of trypanosomiasis and of syphilis. The illustrations are good but rather few; the text is admirable, though the translation is hardly idiomatic. As a manual of hematology, this book is complete. Later volumes may be expected to present in detail the clinical aspects of certain blood diseases in the light of the progress of the past ten years.

THE BOSTON
# Medical and Surgical Journal.

THURSDAY, MAY 11, 1911

*A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.*

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

## DRESDEN INTERNATIONAL HYGIENE EXPOSITION.

THERE is at present in progress at Dresden, Germany, an International Hygiene Exposition, which was opened on May 1 and will continue until Oct. 31, and which is intended to represent on an elaborate scale the progress made by this science during the past twenty-five years. Preliminary details of the project have been at hand for some time. In fact, the exposition was first planned as long ago as 1903, and a convention to prepare for it was held at Dresden in 1906. Since then, preparations have been steadily under way, and the arrangements have been completed during the current spring.

The exposition is divided into twelve general sections. The first will demonstrate the relations of light, air, soil and water to human health. The second will deal with housing conditions. The third considers foodstuffs and nutrition, the scientific value of foods and their practical handling. The fourth comprises clothing and bathing. The fifth includes professions, trades and occupation diseases. The sixth deals with infectious diseases; the seventh with nursing and aid; the eighth with children and adolescents; the ninth with traffic and its relation to disease; the tenth with army and navy hygiene; the eleventh with vital statistics; and the twelfth with burial and cremation.

In addition to these general divisions, there are special sections on tuberculosis, sex hygiene, alcoholism, cancer, dental and oral hygiene and the history of sanitation. There is also a section on popular sports, in connection with which will be held numerous athletic and gymnastic exhibits, games and competitions, notably an international swimming contest on June 18 and a national men's swimming contest on July 30. Special exhibits have been sent by many nations, especially by China, to illustrate its progress in the art of architecture.

In conjunction with the several sections are to be held in Dresden, also, during the summer, meetings of numerous learned, scientific and technical societies. One of these, the German Association for School Hygiene, has already had its sessions on May 6 and 7. On June 8 will be the meeting of the Association of Medical School Inspectors; and on Aug. 2 to 5 will be held a Temperance Congress. Other organizations that will meet at Dresden this summer are the German Society for the Hygiene of the Races, the National Society of German Engineers, and the Association for the Study of States' Science.

Hardly any European city could have been better selected for such an exposition than Dresden. As the capital of Saxony, it is a seat of wealth, power and dignity; and it is, besides, a community of notable cultivation and enlightenment. Superbly situated, architecturally imposing, with rich treasures of art and science, Dresden is a center of German civilization. The spacious grounds of the Brühl, the Zwinger and the Volksgarten, and the buildings of the Zwinger, the Albertinum and the Johanneum afford admirable location for the various exhibits. The demonstrations of progress and methods in hygiene should be notable, and there could not be a more appropriate scene than Dresden for this exposition of what is perhaps most characteristic in the advances of twentieth-century science.

## AN UNCROWNED KING.

THE Regent Luitpold of Bavaria, now a nonogenarian, has since 1886 ruled with kingly power over a people mightily affectioned toward him; he wears no crown, because King Otto still lives, hopelessly insane, and because the Bavarian constitution makes no provision for the deposition of its sovereign. Nevertheless Prince Luitpold occupies the securest of thrones — one that is fixed in the hearts of his subjects. He embodies the rugged Bavarian virtues; kindly, generously simple of nature, his subjects feel him to be one of themselves, though far above them, and a father to them all.

We may here not further extol his manifold excellencies except to note, as altogether characteristic of the man, his refusing any costly and elaborate celebration of his ninetieth birthday; he expressed but one wish, that when it came

(on March 12, last) the public should, if it pleased, establish a charitable fund, the income of which should be used for the common welfare, and for philanthropic purposes.

A score of years ago Kaiser Wilhelm wrote in the Golden Book in the town hall of Munich, the Bavarian capital: *Suprema lex regis voluntas.* But Luitpold showed himself a truer ruler and a wiser controller of human destinies when he wrote in that same book, a few years after, his own guiding motto: *Salus populi suprema lex,* — the health of the people is the supreme law. The Prince Regent thus sensed better than the Emperor that the happiness and prosperity of any nation, its most precious assets indeed, lie in the health and physical welfare of its people. And we may assume the Kaiser has seen some light since his inscription twenty years ago in that Golden Book, for he applauded the oldest living monarch on his ninetieth birthday as "the incarnation and model of all the princely virtues."

## A NEW PREGNANCY CLINIC.

ON Friday, May 5, was opened, at 33 McLean Street, the new Pregnancy Clinic of the Boston Lying-In Hospital. The purpose of this new department of the hospital is to afford to all prospective patients, both house and out-patient cases alike, such care and observation during their pregnancy as they should and would receive at the hands of a good private physician; with a view not only to the early detection, the prevention or the proper treatment of the more serious complications of pregnancy, but also to the hygienic education and training of patients in such manner as shall best prepare them for labor and shall tend to promote normal and healthy fetal development. To this clinic also all house and out-patients, on discharge, will be referred for observation and treatment of difficulties in lactation and other post-puerperal complications.

In this manner it is hoped in time to keep every patient under efficient observation and guidance for a period of approximately two years, from the beginning of pregnancy to the establishment of the baby on independent feeding. The work of this clinic, it is believed, should be of service not only to individuals by prevention or timely avoidance of serious trouble, but also to the community and to the medical profession, by demonstration of the methods and diffusion of a realization of the importance of extending the obstetrician's work from the brief periods of labor and puerperium over the periods of pregnancy and lactation as well. General application of such methods should conduce to the conservation both of maternal and of fetal health and life.

## COMPENSATION FOR INDUSTRIAL ACCIDENTS.

LAST year a commission was appointed by the Massachusetts State Legislature "to determine upon a plan of compensating employees for injuries sustained in the course of their employment." This commission has been continued by the present General Court, and in connection with its investigations has supplied to every employer in the state suitable blanks upon which he is requested to report to the commission the details of every accident occurring to a workman in his employ. This co-operation of employers is invited in order to obtain data upon which to base "an estimate of the probable cost of providing for the relief of injured employees and their dependents."

The principle of compensation for industrial accidents has in it elements of danger in the possible subversion of the care, wholesome pride and instinct of the individual in looking out for himself. Before it is established, therefore, it deserves careful consideration in every aspect, and it is to be hoped that employers throughout the state, by making prompt and thorough report on all accidents and injuries, will cordially aid the present commission in giving the subject a complete and adequate investigation.

## REPORT OF BOSTON STATE HOSPITAL.

THE second annual report of the trustees of the Boston State Hospital describes the work of this institution for the year ending Nov. 30, 1910. It refers particularly to progress made in the construction of the proposed new "psychopathic hospital for the first care and observation of acute cases," which it is expected will be ready to receive patients in the spring of 1912.

The superintendent's report shows an increase of seventy-one in the number of patients under care at the close of the year. It describes particularly an epidemic of paratyphoid which occurred in the hospital during October, 1910, and the method of antityphoid inoculation which was employed for the protection of house officials and employees.

A special report describes the research work done by Dr. Morse on comparative morphologic, cultural and biologic study of different strains of

diphtheria bacilli with a view to determining a method for their differentiation, in routine diagnosis, into pathogenic and diphtheroid forms. The report of the superintendent of nurses notes the policy of increasing the number of women nurses in the male wards, and the change to a ten-hour day of service for all nurses.

## INCREASE OF SUICIDE IN THE UNITED STATES.

In an address last week before the New York Teachers' College, Frederick H. Hoffman, statistician of the Prudential Company, presented striking figures relative to the increase of suicide in this country. In the 65 largest American cities there was in 1890 an annual suicide rate of 12.3 to every 100,000 of population. In 1895 the rate was 15.8; in 1904 it was 20.7; and since 1907 it has remained above 20. The highest actual rate in a single city was 60 in San Francisco. Oakland, Cal., stood second; and Hoboken, N. J., came third, with a rate of 52.6.

These statistics are impressive. The factors which determine suicide are probably manifold. Doubtless the fundamental cause is in all cases the same, a primary defect in mental stability. But the predisposing and occasioning causes are many, and these causes seem to be produced by the life of modern urban civilization with increasing frequency.

## MEDICAL NOTES.

An English Centenarian. — Miss M. B. Cobbett, of Exeter, in Devonshire, celebrated on March 29 the supposed one hundred and first anniversary of her birth. She was born in London, but has resided in Exeter for forty-six years. She is said to be in excellent health.

Proposed Tax on Proprietary Medicines. — Report from Washington, D. C., states that a bill introduced on May 6 before the national House of Representatives, and referred to the Ways and Means Committee, provides "a stamp tax of one eighth of a cent on every five cents' worth of proprietary medicines, perfumes, cosmetics and similar articles prepared under secret or privately owned formulæ."

A Prolific Father. — Report from Wilkesbarre, Pa., states that, on May 7, a twenty-fifth child was born to Mr. Nathan Valone, of the neighboring town of Pittston. Mr. Valone, who has been twice married, had by his first wife 16 children, of whom 14 are now living. By his second wife he has already had, in ten years, 9 children, of whom 8 are living.

Illness of King Alfonso. — It is reported from Paris that King Alfonso, of Spain, has been ordered by his physicians to Lezins, Switzerland, to be treated there for tuberculosis of the throat. The king, whose health has always been delicate, is not yet twenty-five years old. His father, Alfonso XII, died of phthisis at the age of twenty-eight. It is also stated from Madrid that the King's second son, Prince Jaime, is soon to have his tonsils and adenoids removed. The ailments of commoners affect kings as well.

Russian Method of Preserving Meat. — In a recent communication from St. Petersburg, the military attaché at the American embassy in that city describes a new process of preserving meat, recently invented by Dr. Michael Vlasevich, a Russian military surgeon. This process consists essentially in dipping the carcass into a tank of strong acetic acid, then hanging it in the air to dry. Carcasses thus treated are said to keep a long time and to remain good for food.

Central Bureau for Medical Instruction. — From Berlin is reported a project for the betterment of medical education by the establishment in that city of a central bureau of the international committee for post-graduate medical instruction. It is intended that this bureau shall act as a clearing house for all persons pursuing graduate education abroad. A similar system might to advantage be organized in this country to co-ordinate graduate instruction at the different universities.

Sterilization of Criminals in New Jersey. — It is reported that on May 4 the governor of New Jersey signed the so-called "sterilization bill," recently passed by the legislature of that state, providing for the asexualization of criminals and defectives. A board of examiners is to be appointed to carry out the law. New Jersey is the fourth state in the Union to enact such a measure, similar laws being already operative in Indiana, Connecticut and California.

Dinner to President Taft. — On Thursday, May 4, a dinner and reception were given by the Philadelphia Medical Club in honor of President Taft, who was the guest of the occasion. Andrew Carnegie and John D. Rockefeller were also among those invited, in recognition of their services in the promotion of research in preventive

medicine. At the reception addresses were made by President Taft; by Dr. S. Weir Mitchell; by Dr. William H. Welch, on "The American Medical Association"; by Dr. Charles A. L. Reid, on "National Medical Legislation"; by Surgeon-General George H. Torney, on "The Army Medical Corps"; and by Surgeon-General Charles F. Stokes, on "The Medical Corps of the Navy."

POSTPONEMENT OF INTERNATIONAL OPIUM CONFERENCE. — Report from London, on May 6 states that the negotiations between England and China for the restriction and ultimate extinction of the opium traffic to China from India, to which we referred in last week's issue of the JOURNAL, have been successfully concluded, and that India has agreed to reduce her annual exportation of opium at such a rate that it will cease entirely in 1917. It is further announced from Washington, D. C., that the International Opium Conference, which was to have met at the Hague next July, has been posponed for a year, owing to the unreadiness of Germany, Japan and Portugal to present the requisite data relative to their own opium trade.

SOME ADVERSE OPINIONS OF DOCTORS. — In a review of Dr. Robert N. Willson's book on "Medical Men in the Time of Christ," the *British Medical Journal*, describing the Jewish practitioners of that era, quotes from the Talmud a passage stating that it is legitimate for them "to heal Gentiles only for the sake of the fee, but not to save their lives in seasons of danger." Apparently doctors were not held in high esteem in those days, for the Talmud elsewhere avers that "all ass-drivers are wicked, camel-drivers are honest, sailors are pious and physicians are destined for hell." (*Medicorum optimus dignus est Gehennae.*) This opinion of doctors has been shared by some of later date. Perhaps even the "Religio Medici" has diffused the belief that "*ubi tres medici ibi duo athei.*" Granting the worst that may be said of us, we may at least rejoin to such critics, in the modified words of Omar:

> "Of our base metal may be filed a key
> That shall unlock the door they howl without."

## BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, May 2, 1911, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 49, scarlatina 40, typhoid fever 12, measles 199, smallpox 0, tuberculosis 72.

The death-rate of the reported deaths for the week ending May 2, 1911, was 18.01.

BOSTON MORTALITY STATISTICS. — The total number of deaths reported to the Board of Health for the week ending Saturday, noon, May 6, 1911, was 260, against 235 the corresponding week of last year, showing an increase of 25 deaths, and making the death-rate for the week, 19.68. Of this number 140 were males and 120 were females; 256 were white and 4 colored; 166 were born in the United States, 86 in foreign countries and 8 unknown; 55 were of American parentage, 169 of foreign parentage and 36 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 46 cases and 6 deaths; scarlatina, 34 cases and 2 deaths; typhoid fever, 9 cases and 2 deaths; measles, 187 cases and 2 deaths; tuberculosis, 94 cases and 27 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 36, whooping cough 3, heart disease 30, bronchitis 6. There were 17 deaths from violent causes. The number of children who died under one year was 43; the number under five years, 67. The number of persons who died over sixty years of age was 72. The deaths in hospitals and public institutions were 113.

ST. MARGARET'S HOSPITAL. — On Sunday, May 7, the new St. Margaret's Hospital, Dorchester, was dedicated with appropriate ceremony, and opened for the inspection of visitors. This hospital, which is to be an adjunct to the St. Mary's Infant Asylum, was founded by the Rev. Peter and the Rev. Michael Ronan, in memory of their mother, who died several years ago. It is intended chiefly for obstetric but to a certain extent also for general surgical cases.

POLIOMYELITIS IN PROVIDENCE. — On May 1 was reported at Providence, R. I., the first case of acute poliomyelitis known to have occurred in that state this year.

A LIVING CENTENARIAN. — Benjamin Priest, of Canaan, Me., who is locally reputed to have been born in 1811 at Waterville, Me., celebrated last week the supposed centennial anniversary of his birth. He is said to have enjoyed excellent health all his life.

PENALTY FOR TEARING DOWN A MEASLES PLACARD. — In the Malden (Mass.) District Court last week, a resident of the adjacent town of Melrose was fined $10 for tearing down from his

house a notice posted there by the local board of health stating there was a case of measles within.

Fine for Practicing without Registration. —Before the Newton (Mass.) District Court last week, a resident of West Newton was fined $100 for practicing medicine without a registration certificate. The defendant, who styles himself "optologist, refractionist and optical masseur," and who claims to cure blindness and other ocular ailments by lights, lenses and optic gymnastics, appealed from the decision of the court and was held in $300 bail.

Protection of Foods Exposed for Sale. — In the issues of the Journal for March 16 and May 4 we noted the purpose of the Boston Board of Health to enforce the rule requiring foodstuffs exposed for sale to be protected from dust and flies. Strenuous objection to this ordinance has been made by many dealers, one of whom has absolutely refused to comply, in order that he may be prosecuted and make his case a test of the validity of the regulation.

A Leper from Pawtucket. — Last week a case of leprosy was discovered in Pawtucket, R. I. The patient, a boy of fifteen, who came north from New Orleans five years ago, is at present under quarantine at his home in Pawtucket. Attempt is being made to arrange with the Massachusetts State Board of Charity to have him transported to the leper colony on Penikese Island, off New Bedford.

Infant Mortality in Boston, New Bedford and Fall River. — In a recent address before the New Bedford (Mass.) Medical Society, Dr. John M. Connolly, of Boston, presented statistics relative to the high infantile death-rate prevailing in New Bedford. In the year 1909, 47% of the total deaths in that city were of children under five years and 34% were of children under one year of age, figures exceeded in this state only by Fall River. In Boston during 1910 the infantile death-rate was 4.3 per thousand of population; in New Bedford it was 8.5. These data merely reiterate well-known facts relative to infant mortality, but should serve to emphasize them in such way as to promote the efforts at improvement already on foot.

Studies in Occupational Hygiene. — The monthly bulletin of the Massachusetts State Board of Health for March contains a paper entitled "Practical Studies on Occupational Hygiene," by Dr. Elliott Washburn, state inspector of health of Norfolk and North Bristol counties. The author describes numerous observations in regard to the sanitary conditions of workers in various trades that may be made and recorded by inspectors in connection with their routine duties, and points out the immediate practical value of data thus collected in inquiries relative to the causes of disease, the sources of mortality and the effects of localities, conditions and circumstances on the public health.

Medical Women's Association. — There has been organized in Boston recently the "Medical Women's Association for Aiding Women in Medical Work in Foreign Countries." Its purposes are "to raise money to endow already existing medical institutions for women, to provide scholarships for native women in medical schools, to take a personal interest in women medical students studying to enter the foreign fields, and to provide equipment and hospital facilities." Two sections have been formed, one for India and one for China. The officers of the new organization are as follows: President: Dr. Frances M. Morris. Vice-Presidents: Dr. Helen I. Woodworth, Dr. Edith Hale Swift. Treasurer: Dr. Mary R. Mulliner. Secretary: Dr. Blanche A. Denig.

Some Bequests in Medical Charity. — The will of the late Sarah Elizabeth Read, who died in Boston recently, was filed for probate last week. Among many charitable bequests, it contains legacies of $5,000 each to the Channing Home and the Willard Hospital for Dipsomaniacs, Roxbury.

The will of the late Mrs. Elizabeth O. P. Sturgis, filed last week for probate at the Essex County Probate Court at Salem, Mass., contains bequests of $20,000 each to the House of the Good Samaritan, the Kindergarten for the Blind, the Boston Nursery for Blind Babies and the Industrial School for Crippled and Deformed Children.

The will of the late Joseph W. Leighton, of Brookline, Mass., who died on April 26, was filed last week for probate in the Norfolk Probate Registry at Dedham, Mass. It contained numerous charitable bequests, among them one of $75,000 to the New England Home for Little Wanderers, and one of $12,000 to the Children's Hospital, Boston.

## NEW YORK.

BEQUESTS. — Among the charitable bequests in the will of the late Charles Engert, of Brooklyn, are the following to Brooklyn institutions: $10,000 to St. Catharine's Hospital, and $5,000 each to the German Hospital and to St. Mary's and St. Peter's hospitals.

TESTS OF SARATOGA SPRINGS WATER. — State chemist Thomas Conkling reports that recent tests made by him show that the water of one of the springs at Saratoga, Hathorn No. 1, which was injuriously affected by the suction of carbonic acid gas pumped for years by a commercial company from the mineral springs basin, is now regaining its former activity and medicinal properties. All such pumping has been permanently stopped, and there is thus ground to believe that, under the scientific management of the State Reservation Commission, the exhausted springs will again rise naturally, and Saratoga be restored to its pre-eminence as an American health resort.

CENTENARY OF Dr. JOHN WILLIAM DRAPER. — The centenary of John William Draper, M.D., LL.D., scientist, inventor, historian, philosophical writer and teacher, who was for many years professor of chemistry and physics at the university, was celebrated at New York University on May 5. Professor Draper was the first to take a photograph of the human countenance (his sister, Catharine Draper, being the first person whose portrait was made in this way), and also the first to photograph the moon, and it was largely through his advice and assistance that Prof. S. F. B. Morse was enabled to bring his telegraphic system to successful fruition. At the memorial exercises Dr. John J. Stevenson, professor emeritus of geology, presided, and among those who made addresses were Dr. Egbert LeFevre, dean of the University and Bellevue Hospital Medical College, and Professors Lamb, Bristol, Henschel and M. B. Brown. Resolutions eulogistic of Dr. Draper, which had been recently passed by the Board of Aldermen, were read by Francis P. Bent, vice-chairman of the board, and in honor of the occasion the City Hall, by order of Mayor Gaynor, was decorated with national, state and municipal flags. The occasion was a dignified and appropriate tribute to the memory of an early and distinguished American physicist.

PURE MILK FOR NEW YORK. — The contract for supplying pure milk for the sixty stations to be opened by the committee on reduction of infant mortality of the New York Milk Committee has been awarded to the New York Demonstration Company. This company, which was organized only recently, established a plant and laboratory at Homer, Cortland County, N. Y., for experimenting on certain well-defined plans proposed by Dr. Charles E. North, bacteriologist of the milk committee, with the idea of furnishing absolutely pure milk of high quality at less cost than the prevailing prices. It has agreed to supply for eight cents a quart guaranteed milk, bottled at the dairy, of practically the same grade as that for which the high-class dealers charge fifteen cents. The plant at Homer, which is in charge of a competent bacteriologist, has a capacity of 8,000 quarts of milk daily, although the present contract with the committee calls for only 4,500 quarts.

COLUMBIA UNIVERSITY — GIFTS, APPOINTMENTS. — At the meeting of the trustees of Columbia University on May 1, it was announced that a gift of $40,000 had been received from an anonymous donor for surgical research, of which sum $10,000 is to be expended for this purpose each year for four years. Dr. Henry Pike was appointed assistant professor of physiology. Dr. Pike is a graduate of Indiana University and of the University of Chicago, and has been connected with the latter institution since 1903. Another appointment made was that of Dr. Warfield T. Longcope, of the University of Pennsylvania and the Pennsylvania Hospital, to be assistant professor of medicine, and Edward Kempton Adams, professor of experimental physics in Johns Hopkins University, was named Edward Kempton Adams Research Fellow for 1911–12. The title of Henry Fairfield Osborn, Sc.D., was changed from DaCosta Professor of Zoology to Research Professor of Zoology.

OPENING ROCKAWAY BEACH HOSPITAL. — The Rockaway Beach Hospital, in the Borough of Queens, a free institution, built at a cost of $100,000, was formally opened on April 30. Addresses were made by clergymen of different churches, and the hospital was accepted on behalf of the city by Commissioner of Public Works Dunn. There was singing by school children, and before the exercises a parade of 1,500 persons representing various religious, civic and political societies.

WORK OF THE "FLY" COMMITTEE. — A special feature of the campaign the "Fly" Committee of the American Civic Association, which was

organized last year, has undertaken is to be the enlistment of the interest of children, and Edward Hatch, Jr., of New York, has offered cash prizes to the pupils of public and parochial schools in various cities of the country for the best essays on "The House-fly as a Carrier of Disease." He believes that in this way not only will the children be made familiar with the sanitary lessons it is desired to inculcate, but the parents, through their interest in the preparation of the essays, will come to realize the dangers resulting from the fly pest and exert themselves in its suppression. In New York, the prize plan will have its first trial in the schools of the Children's Aid Society, whose teachers have already received the committee's bulletin entitled, "Beware of the Dangerous House-fly," for distribution among the pupils, in order to afford material for the essays. The committee has had prepared a traveling fly exhibit, which is now on view at the American Museum of Safety on West 39th Street, and it is purposed to loan it to such organizations as make application for it. In Rochester, it is planned to have the moving picture film, "The Fly Pest," exhibited in the public and parochial schools during the entire month of May. This is the film which has been introduced in many of the motion picture shows through the influence of the committee, which has found it one of its most powerful educational agencies.

## Current Literature.

### Medical Record.

April 29, 1911.

1. *Conner, L. A. *Pulmonary Symptoms as Premonitory Signs of Venous Thrombosis.*
2. Hayes, W. V. *Street Sanitation in New York, with Some Suggestions for Its Improvement.*
3. Austin, C. K. *A Case of Multiple Myeloma with Albumosuria.*
4. Weinstein, J. W. *Drugs in Gastric Therapeutics.*
5. Crothers, T. D. *The Significance of a History of Alcoholic Addiction.*
6. Dawbarn, R. H. M. *Short Talks with My Students and Others; Being Random Suggestions for the Younger Practitioners.*

1. Conner believes that the percentage of cases in which pulmonary embolism complicates venous thrombosis is larger than is generally supposed. Pulmonary symptoms are often the first indication of a beginning venous thrombosis. They are the result of the lodgment in branches of the pulmonary artery of emboli, derived from the newly formed friable thrombi in the peripheral veins. The symptoms are frequently slight and transient, one or more of the cardinal symptoms — thoracic pain, distress, cyanosis, air hunger, cough, hemoptysis, chills — often being lacking. The physical signs are either those of plastic pleurisy or of a small area of consolidation. The chances of pulmonary embolism are greater at the beginning of a venous thrombosis than later on in its course. Some of the obscure chills in typhoid fever are related to the lodgment of pulmonary emboli. [L. D. C.]

9. Kennedy, J. C. *Is Antitetanic Serum a Factor in the Cure of Tetanus?*

3. Wise gives the following absolute contra-indications to the use of salvarsan: Aortic insufficiency or stenosis, aneurysm, myocarditis, angina pectoris, peripheral arteriosclerosis, cases prone to cerebral hemorrhage, diseases of the central nervous system involving vital organs, severe retinal and optic nerve lesions, diabetes, gastric ulcer, advanced pulmonary disease (except tuberculosis), advanced renal disease of non-syphilitic origin.

6. Dr. Rambaud, director of the New York Pasteur Institute, corrects a few popular misconceptions in regard to hydrophobia. The laboratory, he reminds us, can clear up a doubtful case within a few hours in ninety out of every one hundred instances. The Negri bodies, when present, prove in 199 cases out of 200 that the animal was rabid. Their absence means that with a probability of 90% the animal was not rabid. In such a case inoculation will settle the question within twenty days. The bite of a rabid dog is harmful to man in proportions varying from 10 to 90%, according to different conditions.

1. The advances made during the past year in placing the etiology of beriberi on a scientific basis have now proceeded far enough to warrant the inference that prophylactic medicine has the knowledge at its command to place this scourge among the preventable diseases. It has been found that polished rice or that from which the pericarp has been largely or wholly removed is a large factor in the production of beriberi. This polished rice contains only 0.4 of phosphorus pentoxid, while the unpolished rice contains from 0.5 to 0.75 of the phosphorus and is a beneficial diet. It is thought that the total exclusion of polished rice will almost entirely stamp out beriberi in the districts where rice is the staple article of food and where meats are not eaten.

2. Kessel believes that far too great stress has been laid on the incidence of premenstrual fever in tuberculosis.

He found only two cases in one hundred. This is contrary to the reports found in literature. [E. H. R.]

1. Rous has succeeded in transmitting a sarcoma of the chicken by the injection of a cell-free filtrate of the tumor which had been passed through a Berkefeld filter of medium size. The original tumor possessed all the characteristics of a true malignant neoplasm both in morphology and in behavior. The original tumor in the chicken produced extensive metastases. The tumors produced by the cell-free filtrate were of distinctly slower growth than the tumors produced by the usual implantation. In some instances, in addition to the growth at the site of inoculation, metastases were found after the injection of the tumor filtrate. Rous presents two hypotheses: (1) That the cell-perpetuating agent in this sarcoma is a minute parasitic organism; and (2) that the tumor is caused by some chemical stimulant. The article with the accompanying plates is very convincing and contributes an extremely important piece of evidence in the study of the etiology of malignant disease. [R. I. L.]

11. HIRSCH, C. T. W. *Motoring Notes.*

1. In the second of the Milroy Lectures, Boycott, in an interesting way, discusses the diagnoses of ankylostoma infection with special reference to the eosinophilia as here found compared with the same phenomenon in other parasitic affections. He then discusses the conditions which determine the prevalence of ankylostoma infection, oxygen, warmth and moisture, with relation to these conditions as found in the Cornish mines.

2, 3, 4. Godlee, Makins and Bowlby, in three short separate articles, briefly describe cases of injury to the periosteum, following trauma, which was followed by the formation of bone in the periosteum.

6. Macdonald has made a study of eighty diphtheria carriers. The control of this disease depends on the control of the carrier in his opinion; due quarantine of the carrier should be rigidly enforced regardless of age, sex or other conditions until the organisms have entirely disappeared. [J. B. H.]

1. In the third lecture on ankylostoma infection, Boycott discusses treatment and prophylaxis. He observes that it is easy to cure a man of ankylostomiasis but extraordinarily difficult to cure him of ankylostoma infection. Most patients will markedly improve on getting rid of a constant source of infection. Four drugs are commonly used — thymol, B naphthol, eucalyptus oil and male fern. The Porto Rico Commission in treating 300,000 cases discarded male fern as useless, eucalyptus as too nauseating and B naphthol as dangerous in that it sometimes caused a fatal nephritis in already diseased kidneys. One or two doses of thymol will usually restore a man to such a degree of health that he feels quite well and able to work, though in many such a residuum of worms will still be present in the bowel. He goes on to describe the measures taken in the mines in Westphalia, Germany, and the results obtained, and also the steps taken in Belgium, Cornwall and the tropics, presenting many statistical tables.

5. Hutt, in examining large numbers of school children from the age of seven to fifteen years, found a slightly enlarged thyroid in 99 out of 3,982 cases. He comments briefly on these findings, but draws no definite conclusions.

8. The writers were able to cause regression of inoculated new growths in rats by injections of serum from a horse suffering with epithelioma. They also found that it was not possible simultaneously to produce immunity against cobra venom and to retain susceptibility to new growth inoculation in mice and rats, or conversely, after

successful inoculation with tumor, to produce immunity to cobra venom. If the tumor were already present the animal succumbed to sublethal doses of cobra venom, and, conversely, in those animals in which immunity to the venom could be established, growths which had already reached a size of 1 cm. in diameter would regress. Continuing this, they experimented with antivenom injections in animals inoculated with caries as to the ratio of tumor weight to body weight at which it was possible to cause regression. [J. B. H.]

7. Thomas, J. L. *The Eye of Surgical Needles; a New Form.*

1. *Cf. British Medical Journal*, April 8, 1911.

2. Freyer comments on a series of 200 cases of total enucleation of the prostate in which there were only 9 deaths, a mortality of 4.5%.

3. Raw has come to the conclusion that human and bovine phthisis are antagonistic in the human body and that children who have suffered from bovine tuberculosis in the form of glands, joints, etc., are immune against consumption and that persons who have developed consumption are immunized against the surgical forms of the disease. He supports this theory on the ground that Von Behring, in producing immunity against tuberculosis in cattle, could only do so by using the human strain of bacilli. Raw's results in treating pulmonary tuberculosis with human tuberculin, Koch's T. R., have been very disappointing; recently he has been using a form of bovine tuberculin with much better results. He describes his cases, 28 Stage I, 65 Stage II and 15 Stage III, 108 in all. He started in with 1-10000 mgm. and gradually increasing up to the maximum dose of 1–100 mgm., never exceeding this dose. He uses along with this treatment the regular hygienic measures ordinarily used. Of the 28 first stage cases, 18 are arrested; of the 65 second stage cases, 41 are apparently cured, 16 relapsed, 3 progressing and 5 have died; of the 15 third stage cases, 3 have recovered. He believes that tuberculin is a valuable aid to the other methods of treatment but must be used with great care and discrimination.

4. Robertson describes in detail 3 cases of acute inflammation of the thyroid gland. Such cases fall into two classes: (1) in which the gland was previously normal and (2) in which the gland was already goitrous. Out of 96 cases he has collected, in 33, or 34%, the gland was already enlarged. He describes epidemics of this condition. Of the etiology, little is known. The symptoms vary according as the inflammation of the gland is a primary infection or arises in the course of some pre-existing disease, such as pneumonia, rheumatic fever or typhoid. Cases terminate by resolution or go on to suppuration or rarely gangrene. The usual duration is fourteen days. In 27 of the 41 cases in which suppuration occurred there was a pre-existing goitre. The condition must not be confused with (1) simple parenchymatous enlargement; (2) adenitis and cellulitis of neighboring parts; (3) sudden hemorrhage into a cystic thyroid and (4) malignant disease. [J. B. H.]

8. Dawkin, G. M. *The Cardigan Cancer Cures.*

1. Moynihan does not believe that the so-called acute abdominal emergencies are really acute, but are due to factors which have been in existence already some time, and that the acute emergency can usually be prevented by timely recognition of the value and significance of early signs and symptoms.

4. Fenwick demonstrates by means of x-ray plates of kidneys containing stones, the limits of motion of the normal kidney. The knowledge of the presence or absence of such motion is of great value to the surgeon in making both diagnosis and prognosis. He discusses in some detail the significance of such movements, and their absence. [J. B. H.]

7. Gibbs, C., and Calthrop, E. S. *The Curative Effect of Salvarsan Serum in a Case of Syphilis.*

1. Mackenzie, in the first of the Oliver-Sharpey Lectures, discusses the popular conception of heart failure and its associated phenomena usually explained by "back pressure." He speaks of the undue significance given to murmurs, and explains how both tricuspid and mitral insufficiency may be associated with well-functioning hearts and be signs of good rather than bad cardiac action; he emphasises the harmlessness of mitral insufficiency. He then discusses cardiac irregularity and shows of how little value it is as a sign of cardiac incompetency. The real test of the significance of murmurs and irregularities is the fact that they are often found in a man leading an active and strenuous life over a long period. He goes over the same ground in organic murmurs and irregularities. He discusses the "back pressure" theory and what he considers the essential causes of heart failure which are to be found in the heart muscle.

4. Butler, in 100 cases of iritis, found syphilis the cause in 22% and oral sepsis the cause in 12%. This latter he urges attention to as a much neglected factor. In at least 30% of cases it was impossible to ascertain the real cause. Tuberculosis, as a cause, he found present in less than 5% of cases. He does not confirm the views of others that 70% of all cases of iritis are due to syphilis. [J. B. H.]

2. Koenig reports an interesting case of diffuse inflammation of the stomach wall which had been running a subacute course. At the time of operation there were many adhesions and small pockets of acute inflammation. As it seemed inevitable that an hour-glass stomach would result he decided upon resection with favorable results.

9. Christomanos describes the occurrence of kala azar in Greece and endeavors to show the relation between that disease and the rare blood conditions with big spleens, such as Banti's disease. These cases which are like Banti's disease in children he thinks are especially apt to be kala azar. He shows one picture of the parasites, and mentions their use of atoxyl in the treatment. In one case they used salvarsan and on splenic puncture two days later found the parasites still plentiful in the spleen pulp. [C. F., JR.]

2. Schade ends in this number a long and careful article on the formation of concretions. He reaches many interesting conclusions, as follows: The first and commonest kind of stone is formed in layers. The origin of such stones is dependent on the presence of a colloid precipitate. Certain colloids, as fibrin, precipitate in layers. If there is also present a free body in suspension, then these layers will be concentric. When, with these colloids, a crystalline substance comes down, the layer formation will predominate. The simple layer formation is primary, and is followed by more or less definite radiating, crystalline striations. This group of body stones includes the urinary, the salivary, the pancreatic, the intestinal, the inflammatory bilirubin-lime stones of the bile, and also the prostatic and many joint calculi.

The cholesterin stone is peculiar in that it is formed by the confluence of droplets, and subsequent crystallization, and that it has a radiate structure.

For the formation of all the layer stones, the colloids and crystalloids are essential factors.

7. The Rumpel-Leede phenomenon is a tendency to hemorrhage into the skin, which can be demonstrated by putting a Riva-Rocci cuff around the arm and producing a pressure of 45–60 mm. of Hg. for five to ten minutes. The writer supports Leede in the statement that a negative result speaks against scarlet fever, but that a positive one does not indicate much because it occurs in many other diseases. [G. C. S.]

5. WIENER, E. *Quarantine Studies.*

3. From comparative measurements of cretins and normal men, Flinker finds the former to have relatively large heads, short necks, long body and very short legs. This peculiarity indicates persistence on a lower plane of evolution, dependent on inhibition of skeletal growth in childhood. [R. M. G.]

## Obituary.

### HERMAN KNAPP, M.D.

DR. HERMAN KNAPP, the Nestor of New York ophthalmologists, died from pneumonia at his home at Mamaronack, Westchester County, N. Y., on April 30, in the eighty-first year of his age. He was a native of Dauborn, Prussia, and was graduated from the University of Giessen in 1854. From 1864 to 1868 he was professor of ophthalmology at the University of Heidelberg, and while in this position founded the first University Eye and Ear Hospital at Heidelberg. At the time he came to this country (1868) he was considered in Germany as second in his special department only to Von Graefe. In New

York, in 1869, he founded his *Archives of Ophthalmology and Otology*, a journal published both in English and German. Ten years later this was divided into two separate journals. He also founded the New York Ophthalmic and Aural Institute, to which hospital he remained chief surgeon until 1908, when at his request he was made consulting surgeon. Dr. Knapp's international reputation at once gave him a position among the leading ophthalmologists of the United States, and until comparatively recently he labored with great assiduity both in his private and public practice, as well as in his medical literary work, where his contributions were always of great practical value. He was author of a work on "Intra-Ocular Tumors," and of many papers on topics in ophthalmic and aural surgery. Successively he occupied the chair of ophthalmology in the New York University Medical College and the College of Physicians and Surgeons, and 1902 became professor emeritus in the latter. Of late years he had been gradually giving up some of his activities, and in 1910 he definitely retired. He is survived by two married daughters and a son, Dr. Arnold Knapp, who for some time has been executive surgeon of the Ophthalmic and Aural Institute.

## Miscellany.

### EUGENICS: MEETING OF SECTION OF AMERICAN BREEDERS' ASSOCIATION.

The conference of the Research Committees of the Eugenics Section of the American Breeders' Association has just closed a two days' session held at the Monson State Hospital, Palmer, Mass. Dr. W. N. Bullard, chairman of the board of trustees, is also chairman of the section on inheritance in epilepsy. He presided at these meetings. A good number attended from near by and from a distance. Many of these persons are the most prominent in their lines in this country, and much interesting information was given. Such an opportunity as this does not often occur and those who failed to attend have certainly missed a rare chance. Introductory remarks were made by the presiding officer, and the report of the committee on inheritance in epilepsy was read by Dr. Flood. Dr. Carmalt, of New Haven, gave the experience in the enactment and enforcement of the law in Connecticut relating to sterilization. Dr. Ross, the superintendent of the new institution for epileptics located in Mansfield, Conn., gave a short address. Dr. Rosanoff, of the Kings Park State Hospital, read a paper on "Further Studies on Inheritance in Epilepsy." These reports were discussed by Dr. Scribner, of the Worcester State Asylum. A summary was read of the recent report of the commission appointed by Governor Draper to investigate the question of the "Increase of Criminals, Mental Defectives, Epileptics and Degenerates." This report is one of great moment and gives much encouragement from the fact that no positive increase in the number of these defective classes is shown. It is impossible to go into this in detail, but sufficient commendation cannot be given to the method the commission has adopted. Twenty recommendations are made, which are summarized on the last page of the report, and these twenty recommendations are of such consequence that they might well form a test for every state in the Union to study and act upon during the next generation. Dr. E. E. Southard, the pathologist of the State Board of Insanity and Bullard professor of neuropathology in the Harvard Medical School, read the report of the Committee on "Heredity in Insanity," of which Dr. Adolph Meyer is the chairman. Dr. Davenport presented a paper on "Relation between Geographical Isolation and Consanguineous Marriage," with illustrations from New England. Dr. Estabrook gave an account of the degeneracy in Guilder Hollow, a remarkable illustration of the effects of geographical barriers upon degeneracy. Dr. David F. Weeks, superintendent of the New Jersey State Institution for Epileptics, reported the methods that were being studied so as to give uniform plans for charting all cases of degeneracy. This has proved a very difficult subject, but has now developed to such an extent that the Eugenics Record Office will soon issue a bulletin giving the present state of knowledge. These may be obtained by communication with Dr. C. B. Davenport, secretary, Cold Springs Harbor, N. Y. Dr. Henry L. Goddard, director of the research work in the training school at Vineland, N. J., contributed to many of the discussions and read a most interesting paper on the working out of the Binet test in determining the actual age and attainments of children. This test has been applied to thousands of feeble-minded as well as to many thousands of normal children. Mr. Johnston, the superintendent of Vineland Training School, gave his experiences with feeble-minded children. Mr. H. H. Laughlin, the superintendent of the Eugenics Record Office, gave an account of the record work. Dr. McGaffin, pathologist at the Taunton State Hospital, gave a paper on "The Presentation of a Family Pathography." Dr. Houston, of the Northampton State Hospital, discussed some of these papers. Miss Florence Danielson, the social worker of the Monson State Hospital, gave an account of her work. Mr. L. B. Alford, the research officer and pathologist of the Monson State Hospital, gave a most interesting demonstration and discourse on "Inheritance in Epilepsy after the Brown-Séquard Method," with some very remarkable conclusions. The field workers of the different institutions each gave her experience in her own particular field of labor. Dr. Van Nuys, of the Institution for Epileptics in Indiana, discussed the papers. Dr. Mitchell, the superintendent of the Danvers State Hospital, discussed very interestingly several points in the papers. Dr. Provost also participated in the discussion. Dr. Woods, of Harvard University, gave an interesting paper on "Degeneracy among Royalty."

## IN MEMORIAM: DR. PERCY D. LITTLEJOHN.

WE, the members of the New York Urological Society of the American Urological Association, assembled at our stated meeting, this day, April 5, 1911, record with deep sorrow the death of our fellow member, Dr. Percy D. Littlejohn, of New Haven, Conn.

Dr. Littlejohn has been a member of this society for seven years, during which time he has made many friends through his genial and attractive personality. He was a hard student, a close observer and was possessed of the true scientific spirit. These attributes, together with the high character of his work, have made him known and respected by all of the members of this association.

We feel that Dr. Littlejohn's untimely death has deprived us of a sincere friend and a most able fellow worker and that his death is a great loss to our association as well as to the profession in general.

*Resolved:* That we express our heart-felt sympathy to his sorrowing and bereaved family.

*Resolved:* That a copy of these resolutions be sent to the family of the deceased; to the *American Journal of Urology;* the *New York Medical Journal;* the *Medical Record;* and the BOSTON MEDICAL AND SURGICAL JOURNAL.

RAMON GUITERAS, M.D.,
COLIN LUKE BEGG, M.D.,
CLARENCE R. O'CROWLEY, M.D.,
*Committee.*

## Correspondence.

### APPLICATION OF IODINE TO TONSILS.

BOSTON, May 2, 1911.

*Mr. Editor:* Your Paris correspondent "S.," in his last letter upon the uses of iodine as an antiseptic, states that this substance should be of value in the treatment of tonsillar affections. As most of his writings are in advance of the times, I hasten to appraise him of the fact, which, however, he seems to have discovered, that iodine in any solution is useless as a remedy for local use upon tonsils. My own experience with local medicaments compels me to affirm that only those substances which have the property of uniting with the "albuminous" tissues the silver salts and iron solutions can remain long enough upon "tonsils" to do any good. I would recommend Dr. "S." to make use of a solution of iron alum (Fer et Amm. Sulph.) in the nasopharynx and especially over the "Luschka" or first tonsil. I must, however, warn him to watch the kidneys in most acute infectious diseases when doing this.

Very truly yours,
EDMUND D. SPEAR, M.D.

## SOCIETY NOTICES.

AMERICAN SOCIETY OF TROPICAL MEDICINE. — The eighth annual meeting will be held in New Orleans, May 18 and 19, 1911. The morning session of May 19 will be ushered in by a clinic on pellagra at the Charity Hospital. After this the regular scientific session of the society will be held in Hutchinson Memorial of Tulane University. On Saturday, May 20, an excursion is being planned to the Leper Colony.

JOHN M. SWAN, M.D.,
*Secretary.*

NEW ENGLAND HOSPITAL MEDICAL SOCIETY. — The New England Hospital Medical Society will hold its regular monthly meeting at Kensington Building, Boylston Street, May 18, at 7.30. Section on Pediatrics. Subjects: "Review of the Salt and Sugar Fevers of Early Infancy," Dr. Edith Hale Swift. "Prophylaxis of Child Life," Dr. Henry I. Bowditch.

MARGARET L. NOYES, *Secretary,*
32 St. James Ave., Boston.

ESSEX SOUTH DISTRICT MEDICAL SOCIETY. — The annual meeting of the society for the election of officers, and for such other business as may legally come before it, will be held at the Essex House, Salem, Friday, May 12, 1911. Dinner will be served at 7 o'clock. The guest of the evening will be Dr. John Lovett Morse, of Boston, who will read a paper on "Meningitis in Infants."

WALTER G. PHIPPEN, M.D., *Secretary.* GEORGE H. GRAY, M.D., *President.*

## RECENT DEATHS.

DR. HENRY GARRETTSON SPOONER, who died of cerebral hemorrhage at Boston on May 1, was born in this city in 1871. He received the degree of A.B. from Harvard in 1894 and that of M.D. in 1897. After practicing for a few years in Boston, he went to New York City, where he later became the first editor of the *American Journal of Urology.* He was a member of the New York State Medical Society, of the Medical Association of the Greater City of New York, and formerly a Fellow of The Massachusetts Medical Society.

DR. CLIFTON ELLIS WING, who died on May 1 in Jamaica Plain, was born in this city in 1848, the son of a physician. He received the degree of M.D. from Harvard in 1872 and served during the same year as interne at the Boston City Hospital. He practiced medicine in Boston for many years. He was a Fellow of The Massachusetts Medical Society. He is survived by his widow.

## MENINGITIS IN INFANCY.*

BY JOHN LOVETT MORSE, A.M., M.D.,

*Assistant Professor of Pediatrics, Harvard Medical School; Associate Physician at the Children's Hospital and at the Infants' Hospital, Boston.*

MENINGITIS occurs with sufficient frequency in infancy to be well worth our serious attention and consideration. It is safe to say that 75% of the cases of tubercular meningitis occur during the first five years of life and that more cases occur during the second year than at any other time. Cerebrospinal meningitis is more common in childhood than in later life and is especially common in infancy.

When cerebrospinal meningitis is not epidemic, at least 70% of the cases of meningitis in infancy are tubercular. A large majority of the others are meningococcal in origin. It is true that meningitis in infancy is sometimes due to other organisms than the tubercle bacillus and the meningococcus. This happens so seldom, however, that if the symptoms of meningitis do not develop in the course of some other disease it is not necessary, for practical purposes, to consider in differential diagnosis anything but the tubercular and cerebrospinal forms. If the disease is due to some other organism, the symptoms are likely to resemble those of cerebrospinal rather than those of tubercular meningitis. In spite of the apparently better opportunities for the direct extension of suppurative processes from the middle ear to the meninges in infancy than in later life, meningitis from this cause almost never develops at this age.

Symptoms of meningeal irritation are very common in the course of many diseases in infancy, especially in those of the digestive tract, because of the great excitability of the nervous system at this time. When, however, such symptoms develop in the course of other diseases, the presumption is that they are not due to a complicating meningitis but that they are merely the manifestations of cerebral irritation from one cause or another. When the primary trouble is in the gastro-intestinal tract, the nervous manifestations are probably due to the action of toxic substances or high temperature on the brain; when there is severe diarrhea, the loss of fluid probably also plays a part in their production. When the primary trouble is pneumonia or some other acute disease accompanied by high fever, the symptoms are due to the action of toxins and of the fever together with probably a certain amount of cerebral congestion. The nervous symptoms are in many instances due to reflex irritation from a complicating otitis media. They are very seldom due to disease of the kidneys.

The diagnosis between meningitis and nervous symptoms due to cerebral irritation is usually easy when the fontanelle is open. The fontanelle is almost invariably bulging when there is meningitis. It is level or depressed when there is no meningitis. If the fontanelle does not bulge, the trouble is almost certainly not meningitis, although in rare instances the fontanelle is depressed throughout the course of meningitis. If the fontanelle does bulge, a diagnosis of meningitis is justified, the only exception being the bulging of the fontanelle which occurs in the somewhat hypothetical and, at any rate, extremely rare condition of serous meningitis. When the fontanelle is closed, the diagnosis is much more difficult, since the symptoms of meningitis and cerebral irritation may be exactly the same. The general rule still holds, however, that if the symptoms develop in the course of another disease they are in all probability not due to a complicating meningitis. A positive diagnosis can only be made, however, by means of a lumbar puncture. In general, whenever there is any question as to the presence or absence of meningitis, a lumbar puncture should be done. It is a harmless procedure, if performed in a cleanly manner. It is, moreover, not a difficult one and causes no more pain than an injection of antitoxin.

If symptoms of meningeal irritation develop *sui generis*, and a careful physical examination, including the ears, shows no cause for these symptoms, the chances are that the disease is meningitis. It must be remembered, however, that the symptomatology of meningitis in infancy is materially different from that in older children. The pulse and respiration are usually increased in rate, not lowered. Vomiting is more common both as an early and a late symptom. Explosive vomiting is uncommon. Constipation is the exception rather than the rule. Manifestations of pain are unusual. Convulsions are comparatively infrequent. Kernig's sign is inconstant. The knee-jerks are very variable. Ankle clonus is usually absent. Retraction and spasm of the abdominal muscles are almost never present.

It is almost certain, as has been already noted, that in such instances the disease is either tubercular or cerebrospinal. The diagnosis between tubercular and cerebrospinal meningitis at this age is a very difficult one. The rules which apply in older children and adults do not apply at this age. The onset of tubercular meningitis is often acute in infancy, while that of cerebrospinal meningitis is not infrequently slow. The temperature curves vary so much in both conditions that the course of the fever is of but little assistance. The symptomatology of the two conditions after symptoms of meningeal irritation and increased cerebral pressure have developed is practically the same, whatever differences there are being only in degree. On the whole, however, the symptoms of spinal and, to a less extent, of cerebral irritation are more marked in the cerebrospinal than in the tubercular form. Eruptions practically never occur in cerebrospinal meningitis in infancy. Their absence, therefore, does not count against the cerebrospinal form. Their presence is suggestive. The presumption is that, if the baby is less than three months old, the disease is cerebrospinal meningitis, not tubercular. The general condition of the baby is of no im-

*Read before the Waltham Medical Club, Feb. 2, 1911.

portance, because in the vast majority of instances of tubercular meningitis the babies are apparently in good heatlh, the meningitis being the first manifestation of a latent tuberculosis. It is the exception to find evidences of tuberculosis elsewhere.

The absence of a family history of tuberculosis or of a history of exposure to tuberculosis does not count in any way against tubercular meningitis. The history of tuberculosis in the family, when there has been no exposure to members of the family with tuberculosis, counts but little in favor of tubercular meningitis. A history of exposure to tuberculosis is, however, very strong evidence in favor of tubercular meningitis. Such a history can be elicited, if sufficient trouble is taken, in a large proportion of the cases of tubercular meningitis.

The examination of the blood is of some, but not of much, assistance in the differential diagnosis. There is an increase in the number of white corpuscles in almost all cases of cerebrospinal meningitis. There is no increase in most cases of tubercular meningitis. There is, however, a leucocytosis in enough of the cases of tubercular meningitis and little or no increase in enough of the cerebrospinal cases, so that the white count is not of great importance.

The tuberculin test is of some importance. If positive at this age it is strong, but not conclusive, evidence in favor of tubercular meningitis. If negative, it does not by any means exclude it, because this test is often negative in tuberculosis of the miliary type, to which, of course, tubercular meningitis belongs.

In the vast majority of cases a positive diagnosis can only be made by lumbar puncture. Lumbar puncture should be done, therefore, in every case, because if the condition is cerebrospinal meningitis it can be, in many instances, cured by the use of the serum, and because there is no danger in the operation if it is properly performed.

Lumbar puncture is not a difficult operation in a baby. The baby should be placed on its side on a hard surface to prevent lateral flexion of the spine. The spine must then be flexed in the lumbar region by an assistant. It does no good to bend up the knees and flex the chin on the chest if the lumbar region remains straight. When the spine is flexed the spaces between the lumbar spines are enlarged and the needle can be easily introduced. The needle is best introduced between the fourth and fifth lumbar spines. It should be pushed forward and a little upward. It is about 1½ inches into the spinal canal. Care should be taken not to go in too far because of the danger of wounding some vessel on the anterior wall of the canal and causing bleeding. The admixture of blood makes it impossible to tell whether the fluid is turbid or not and interferes to some extent with the microscopic examination of the fluid. There is no danger of a serious hemorrhage into the spinal canal, even if a vessel is wounded, since the bleeding stops as soon as the needle is withdrawn. A line drawn between the crests of the ilia passes through the fourth lumbar spine. There is no danger of wounding the cord at this age if the needle is introduced between the third and fourth spines, and probably none if it is put in between the second and third spines.

The normal cerebrospinal fluid runs out slowly, drop by drop, is perfectly clear like distilled water, does not deposit a fibrin clot on standing, usually contains very few and never more than twenty cells to the cubic millimeter, most of which are small mononuclear, and no organisms.

The normal cerebrospinal fluid contains from 0.05% to 0.1% of albumin; that in tubercular meningitis may contain as much as 0.3%, and that in cerebrospinal meningitis as much as 0.6%. It is, at any rate, always increased in meningitis and is an important point in differentiating between normal and abnormal fluids. A little practice enables one to appreciate any increase at once. Hemenway has recently called attention to the importance of the globulin test of Noguchi in this connection. She always found a positive reaction in meningitis and very seldom in other conditions. The test for a reducing substance with Fehling's solution is so inconstant that it is valueless.

The cerebrospinal fluid in tubercular meningitis is usually under increased pressure and runs out in a stream or in rapidly succeeding drops. It is usually slightly turbid, but may be perfectly clear. A fibrin clot is formed on standing. The fluid should not be considered normal, therefore, even if clear, unless no fibrin clot is formed after six or eight hours. It contains more than twenty cells to the cubic millimeter, usually from one hundred to two hundred. These cells are usually almost entirely small mononuclear, although in rare instances there may be as much as 20% or 30% of polynuclear cells. If the fluid is examined carefully enough, tubercle bacilli will be found in more than 90% of the cases. If it is examined hastily, they will almost always be missed.

The fluid in cerebrospinal meningitis is under increased pressure and usually runs out in a stream. It is turbid or purulent in appearance, forms a fibrin clot or a deposit of pus on standing and contains a great many cells to the cubic millimeter, usually several hundred. The great majority of these cells are of the polynuclear type. The type of cells gradually changes to the mononuclear in the cases which recover. The diplococcus intracellularis, a Gram-negative, biscuit-shaped diplococcus, is found in almost all cases, both within and without the cells.

The fluid in acute poliomyeloencephalitis unfortunately has in many instances the same characteristics as that in tubercular meningitis, that is, it is clear, often deposits a fibrin clot and contains more than twenty cells to the cubic millimeter, most of which are small mononuclear. If the search is careful enough, however, tubercle bacilli will be found in meningitis, but never in encephalitis. A careful study of the symptoms ought, however, to render a diagnosis possible.

*Tubercular meningitis.* — The most striking thing about tubercular meningitis is the irregu-

larity of the onset and early symptoms. No two cases begin in the same way. In some instances the onset is sudden, with very marked symptoms of meningeal involvement; in others it is slow and insidious. It is, however, certainly much more often sudden than is ordinarily supposed. The following histories illustrate very clearly the marked variability of the early symptoms in this disease.

A boy, twelve months old, had been perfectly well up to Feb. 22, when he vomited. The next day he was feverish and coughed considerably. He began to be stupid and to refuse his food Feb. 24. He had no convulsions, spasm or rigidity.

He was comatose when seen Feb. 26. There was no rigidity of the neck. The anterior fontanelle was slightly depressed. The pupils were much contracted. He held his arms and legs rigidly extended. The knee-jerks were equal and lively; Kernig's sign was absent.

A girl, twenty-one months old, began to vomit May 9, after eating chocolate creams. She was thoroughly cleaned out, after which the vomiting gradually diminished and stopped entirely May 17. The bowels became constipated. After May 12 she would sink down to the floor when playing and lie there quietly for a time. She seemed tender all over, so much so that scurvy was suspected. She began to be dull mentally the afternoon of May 19. The physical examination had always been negative. She was seen that night.

She was irritable when disturbed, but did not know where she was or take any notice. The neck was slightly rigid. The pupils were equal and reacted slowly to light. There was no spasm or paralysis of the extremities. The knee-jerks were equal and normal. Kernig's sign, the neck sign and the contralateral reflex were all absent.

A girl, seventeen months old, broke out with the measles Feb. 27. The eruption quickly faded. She began to be a little heavy March 1, and was more so on the 2d and 3d. She was somewhat nauseated on the 5th, but the next day seemed better and brighter, although she vomited. She vomited again on the morning of the 7th and seemed tender over one eye. Loss of power was noticed in the right leg about noon, and twitching of the left side of the face and left arm developed during the afternoon.

When seen that night she was unconscious, there was slight rigidity of the neck and the eyes were turned to the right. The pupils were dilated, equal and reacted slowly to light. There was constant twitching of the left side of the face and of the left arm. The knee-jerk was diminished on the right. Kernig's and Babinski's signs, as well as the neck sign, were absent.

A girl, twenty-one months old, had a cold in the head for several days, beginning Sept. 13. She had a convulsion Sept. 17, after which she seemed nearly well, although she vomited once or twice. There was a serous discharge from the right ear Sept. 24, which stopped in twenty-four hours. Slight spasm of the neck and back and internal strabismus then developed. She was seen Sept. 27.

She was conscious, but took very little interest. There was slight rigidity of the neck. The eyes were turned a little to the right, but the pupils were equal and reacted to light. There was no spasm or paralysis. The knee-jerks were equal and normal. Kernig's sign was absent.

A boy, twenty-seven months old, had had repeated attacks of recurrent vomiting. He began to be croupy April 1. He began to vomit April 3, without known cause and had continued to vomit every few minutes up to the time he was seen, April 6. The bowels had been a little constipated. He had coughed constantly. Physical examination had been entirely negative.

He was somewhat restless, but perfectly clear mentally. The physical examination showed no evidences whatever of meningeal or cerebral irritation, so that a diagnosis of recurrent vomiting was made. Definite signs of meningeal irritation appeared April 9.

A girl, thirty months old, lost her appetite and became a little feverish Feb. 20. Her throat was slightly reddened. Physical examination was entirely negative. Her appetite continued poor, but she did not vomit. There was a tendency to constipation. The temperature varied between 100° F. and 101° F. up to March 1, when it dropped to normal. The pulse was about 110 until March 1, when it dropped to 84. She began to be dull about Feb. 27. This dullness had increased up to the time she was seen, March 4.

She was quiet and took no interest in anything. There was slight rigidity of the neck. The pupils were widely dilated, but reacted slowly to light. The respiration was suggestive of the Cheyne-Stokes type. There was no spasm or paralysis. The knee-jerks were very much diminished. Kernig's and Babinski's signs were absent, as was the contralateral reflex. There was a suggestion of a neck-sign and marked vasomotor irritability of the skin.

It would be easy to multiply examples, all of them different, if it were necessary. In general, however, the early symptoms are referable to the digestive tract and suggest some gastric disorder. This being the case, tubercular meningitis should be thought of whenever a baby vomits without reasonable cause. In fact, in order to make an early diagnosis in every case of tubercular meningitis it would be necessary to mention it as a possibility whenever a baby vomited and, more than that, because of the variability of the early symptoms, whenever a baby was sick in any way. In this way only would no case be missed. Such a course would obviously be ridiculous.

The course of tubercular meningitis in infancy is, as a rule, much shorter than is ordinarily supposed. I have seen a number of cases in which the duration was not more than a week, and one in which it was only thirty-six hours. This patient was under treatment in the hospital for another disease and did not show any signs of meningitis before the acute onset. The diagnosis was confirmed by autopsy. Holt states, in a recent paper, that he has seen but one case in which the duration was as long as five weeks, and that in his experience the average duration in infancy is two and a half weeks. The cases of supposedly long duration are probably not tubercular meningitis, but the chronic form of cerebrospinal meningitis.

Almost every one thinks of tubercular meningitis as a disease constantly associated with rigidity, tenderness and retraction of the neck, opisthotonos, spasm of the extremities, paralysis or spasm of the eye muscles and convulsions. In my experience very marked symptoms of this sort are comparatively unusual. Only a few of them are present, as a rule, in any individual case. It is not uncommon, moreover, for the disease to run its course without any convulsions,

twitching or rigidity, the condition being one of flaccidity with diminished, or absent, reflexes. The following cases are examples:

A girl, fifteen months old, was taken suddenly sick May 13, with vomiting. This was soon followed by a convulsion. She then lapsed into a stuporous condition and took no food, but had no retraction of the head or rigidity. She was seen May 20.

She was then in a deep stupor. The pupils were much dilated, but reacted a little to light. The fontanelle was level, but tense. There was no rigidity of the neck. The respiration was Cheyne-Stokes in type. The abdomen was sunken, but not tense. There was no spasm of the extremities. The knee-jerks and Kernig's sign were absent. Her condition remained the same until her death, May 22.

A girl, four months old, had had a cough and vomited occasionally for two weeks. She was dull, but noticed a little. The fontanelle was bulging and very tense. The pupils reacted slowly to light. There was no rigidity of the neck, and no spasm or paralysis of the extremities. The knee-jerks were equal and normal. Kernig's sign was absent. She died three days later without having developed any spasm or rigidity.

Holt has recently called attention to the fact that tubercular meningitis is more common in infancy during the spring months than at any other time of the year. The most plausible

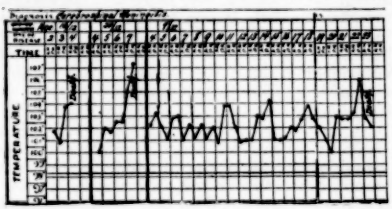

FIG. 1.

explanation of this fact is that pulmonary diseases are most common at this time of year and that they stir up latent tubercular processes in the bronchial glands.

Remissions in the symptoms are much less frequent in infancy than in later childhood. The disease in infancy usually progresses steadily from bad to worse.

Martin [1] has recently collected from the literature since 1894 20 cases of recovery from tubercular meningitis, in which he thinks the diagnosis is certain. Granting that he is justified in this belief, which is somewhat doubtful, this number of cases is so small in comparison with the number of cases of tubercular meningitis which must have occurred throughout the world in the last sixteen years that it does not justify anything but an absolutely hopeless prognosis in this disease. It seems to me that the chances of recovery are so infinitesimally small that it is unfair to hold out the slightest hope of recovery.

The treatment of this disease can, of course, be only symptomatic. It should be carried on, however, as if the baby was certain to get well, because there is always the possibility of a mistake in the diagnosis. The baby should be fed with a tube, if necessary. Bromide or opium in some form should be used to control pain and marked nervous symptoms. Repeated lumbar punctures to relieve the increased cerebral pressure have, however, been more useful in my experience than either bromide or opium. I have frequently seen a baby screaming with pain or having repeated convulsions become perfectly quiet and go to sleep after a lumbar puncture. This procedure has, of course, no curative effect, but does materially diminish the suffering both of the child and of the family.

*Cerebrospinal meningitis.* — Most of the types of cerebrospinal meningitis seen in adults occur in infancy. When the disease is allowed to run its course without being modified by the serum treatment the following types are easily distinguishable:

(1) The malignant or hyperacute, (2) the ordinary, (3) the mild or abortive, (4) the intermittent, (5) the chronic. Every one who has seen much cerebrospinal meningitis in infancy is familiar with all of these types. The most common of them, however, are a type midway between the malignant and the ordinary types and the chronic type. The mild or abortive cases are very uncommon. It hardly seems worth while to give the histories of cases of these different types. The following charts show in a general way, however, the duration and the course of the temperature in the different forms.

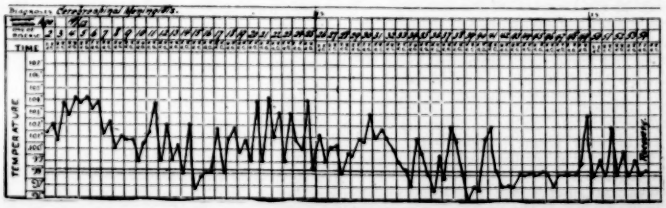

FIG. 2.

Sequelæ are not especially common after cerebrospinal meningitis in infancy when the serum is not used because very few babies live to have them. The most common of them is hydrocephalus, which often develops so early in

[1] Brain, 1909, vol. xxxii, p. 209.

the course of the disease that it deserves the name of complication rather than of sequela. It is not infrequently the cause of death, sometimes after a considerable period. It is due either to an ependymitis or to the mechanical closure of one or more of the foramina. Other sequelæ are spastic paralyses of various sorts from chronic lesions of the meninges, deafness, blindness and mental impairment. In a few instances which I have seen in infancy the mental condition has been almost maniacal. In others there has been a peculiar and persistent tremor.

The prognosis of cerebrospinal meningitis in infancy before the introduction of the serum treatment was practically hopeless, the mortality being between 85% and 100%. This has been materially changed, however, by the serum treatment. Flexner and Joblin, for example, report a mortality of 19 in 44 cases, or only 43%. One of their cases which recovered was only four weeks old.

When the serum is given, the prognosis depends very largely on how early the treatment is begun. The earlier it is begun, the better is the prognosis. Recovery is almost certain unless the disease is of the malignant type, if the treatment is begun within the first two or three days. Recovery sometimes takes place, however, even when the treatment is begun fairly late in the disease. It should always be tried in every case, therefore, no matter how long the duration. The earlier the treatment is begun, the less likely are there to be sequelæ. If begun late, sequelæ may appear as the result of damage done early in the course of the disease. Hydrocephalus is especially likely to develop later as the result of connective tissue formation due to injuries done in the first day or two of the disease.

The chief action of the serum is on the diplococci themselves. It limits their multiplication and causes their rapid death and disintegration. Phagocytosis is also stimulated and the organisms are rapidly taken up and digested. It is for this reason that there are no toxic symptoms from the rapid destruction of the organisms. Since the action of the serum is directly on the organisms themselves, it is very important to have it reach them in as concentrated a form as possible. The serum is so much diluted before it reaches the cerebrospinal fluid, when it is introduced subcutaneously or intravenously, that it is practically inert. It must, therefore, be introduced directly into the cerebrospinal canal. This is best done by lumbar puncture. As much cerebrospinal fluid as possible must be allowed to run off before the serum is introduced in order that it may not be diluted any more than is necessary and that it may reach the micro-organisms in as concentrated a form as possible. The connection between the ventricles and the spinal subarachnoid space is blocked in certain instances. This is shown by the failure to obtain fluid by lumbar puncture. When this happens it is, of course, impossible to get the serum into the ventricles by the lumbar route. In such instances it may be injected directly into the ventricles through the anterior fontanelle. Fischer[2] has recently treated several cases successfully in this way.

The action of the serum is best shown by the changes in the cerebrospinal fluid. Before the serum is given, the organisms are numerous, stain clearly and are both within and without the cells. After the serum is given, the organisms diminish in number and the extracellular organisms disappear. The organisms then stain poorly and the intracellular organisms disappear. The power of growth on culture media is lost before the organisms are entirely gone. At the same time the fluid becomes clearer and the cells stain less distinctly and show evidences of disintegration. The leucocytic formula also gradually changes from one almost exclusively polynuclear to the mononuclear type.

The successive examinations of the cerebrospinal fluid in the following instance demonstrate these changes very clearly.

The patient, a girl sixteen months old, had been ill about two weeks.

April 21. Lumbar puncture. Thirty cubic centimeters of very turbid fluid under moderate pressure were allowed to run off. This fluid formed a large clot, full of yellow pus. It contained a heavy trace of albumin. There were 95% of polynuclear leucocytes and 5% of endothelial cells. A few of the polynuclear cells contained typically arranged and shaped Gram-decolorizing intracellular diplococci, as well as a few extracellular organisms. The culture showed three small colonies of the meningococcus.

A second lumbar puncture was performed that afternoon and 7 ccm. of turbid fluid allowed to run off. Twenty cubic centimeters of the antiserum were injected.

April 22. Lumbar puncture. Fifteen cubic centimeters of rather less purulent fluid, under very low pressure, were allowed to run off. The fluid contained 74% of polynuclear and 26% of large mononuclear cells. The cells all took the stain perfectly. There were a few intracellular but no extracellular organisms. No growth appeared on cultures after forty-eight hours. Thirteen cubic cemtimeters of antiserum were injected.

April 23. Lumbar puncture. Ten cubic centimeters of slightly turbid fluid, under low pressure, were allowed to run off. There was no macroscopic pus. The fluid deposited a spider-web fibrin clot. It contained a trace of albumin. There were 55% of polynuclear and 45% of large mononuclear cells. Many of the cells were degenerating and the outline of the cells was not as clear as before. No organisms were seen and there was no growth on cultures. Fourteen cubic centimeters of antiserum were injected.

April 27. Lumbar puncture. Four cubic centimeters of almost clear fluid, under very low pressure, were allowed to run off. It deposited a very fine fibrin clot. One polynuclear cell, eight lymphocytes and eight endothelial cells were seen on one slide. There were no bacteria, and there was no growth on culture. Fifteen cubic centimeters of antiserum were given.

The serum should be given early in order to get the best results. If the fluid obtained by lumbar puncture in a case of meningitis is markedly turbid or purulent, the serum should be administered at once without waiting for the examination of the fluid. Time is gained in this

[2] Pediatrics, 1910, vol. xxii, p. 222.

way if it is cerebrospinal meningitis, as it probably is; no harm is done, if it is not. The serum should be given daily, and in severe cases twice daily, until the disease is under control. The best guide as to this point is the behavior of the cerebrospinal fluid. The injections must be continued, at any rate, until all the organisms have disappeared, and longer if the fluid is markedly purulent. The study of smears of the fluid gives more reliable information as to the disappearance of the organisms than does the growth on culture media because, as already pointed out, the organisms quickly lose their power of growth outside of the body. In general, the temperature falls coincidently with the disappearance of the organisms, sometimes by crisis, sometimes by lysis. In certain instances, however, it remains elevated, although the organisms have disappeared and the other symptoms have improved. Elevation of the temperature alone is not an indication for the continuance of the injections. The following charts show the behavior of the temperature when the antiserum is given.

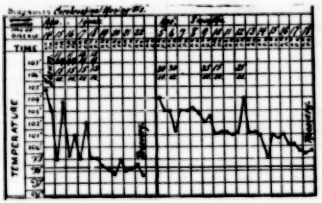

FIG. 3.

It is not uncommon to have rigidity, especially of the neck, persist after the disappearance of all other symptoms. Persistence of rigidity is not of itself an indication for the continuance of the serum treatment.

If the temperature continues elevated and other symptoms of meningeal irritation persist after the disappearance of the organisms and the partial clearing up of the fluid, it is wise to do another lumbar puncture after a few days and, if the organisms are again present or the fluid is purulent, to resume the serum treatment.

As much fluid as possible should be allowed to run out at each tapping in order to prevent dilution of the serum. The amount of serum introduced should at least equal the amount of fluid which has escaped. In any event, at least 15 ccm. should be given, and in older infants 30 ccm., unless symptoms of cerebral pressure develop. If they do, it is easy to let a little of the serum escape and no harm is done. Large doses are necessary in order to get a proper concentration of the serum. If little or no fluid escapes, an attempt to give the serum should be made just the same. If great resistance is encountered, it means that the connection between the subarachnoid space and the ventricles is closed. In such instances the serum must be injected through the anterior fontanelle. The serum should always be raised to body temperature before it is injected.

Many patients are promptly cured by the serum, if it is used early. Almost all are relieved, even if a fatal termination is not averted. In rare instances, however, the serum apparently has no effect. I have seen two such cases. They are at present inexplicable. The results are less satisfactory when the serum is given late. This is especially true in the chronic cases. Even in them, however, the results are sometimes surprisingly good.

*Pneumococcus meningitis.*— Pneumococcus meningitis is more common than was formerly supposed. It usually develops in the course of lobar pneumonia, but the symptoms of meningitis sometimes precede the signs of pneumonia by several days. It is, in all probability, one of the manifestations of a general pneumococcus infection and not a primary condition. It is especially common in the early months of infancy. The symptomatology is so similar to that of the other forms of meningitis at this age, especially the cerebrospinal and influenzal, that a diagnosis is impossible without lumbar puncture, unless the symptoms develop in the course of a pneumonia. The blood, as in all pneumococcus infections, shows a marked leucocytosis. The cerebrospinal fluid is markedly turbid or purulent, the cells are almost entirely polynuclear and the organisms are numerous. The course is almost always less than a week and the end almost invariably death. The following case is a good example of this type.

A girl, five months old, that had always been well, was taken suddenly sick April 6, with convulsions, high fever, cough and labored breathing. She did not vomit. The cough, fever and labored breathing continued. She was admitted to the Infants' Hospital April 9.

*Physical examination.* — She was well developed and nourished. There was moderate pallor. The respiration was grunting and the alæ nasi moved. The anterior fontanelle was 3 cm. in diameter and level. There was no rigidity of the neck. The pupils were equal and reacted to light. Nothing abnormal was detected in the chest. The abdomen showed nothing abnormal. The liver and spleen were normal. There was no paralysis, but slight twitching and rigidity of the extremities. The knee-jerks were equal and exaggerated. Kernig's sign was absent.

The urine was pale, slightly acid in reaction and contained a slight trace of albumin.

Five cubic centimeters of very turbid fluid under low pressure were obtained by lumbar puncture. This fluid deposited a fibrin clot but remained cloudy. A smear showed 95% of polynuclear and 5% of mononuclear cells. Very many Gram-staining diplococci were found both within and without the cells. They were surrounded by a capsule, were pointed at the ends and showed a tendency to form chains. No cultures were made.

She began to have mild convulsions with constant twitching the morning of the 31st. The convulsions soon ceased, but the twitching continued. Rigidity of the extremities developed at the same time and continued until death. The fontanelle was always level or somewhat depressed. The neck was never rigid.

The pupils were dilated and reacted but little to light. The knee-jerks were always exaggerated. Kernig's sign was never found. Signs of solidification at the right apex developed April 15. She died April 17.

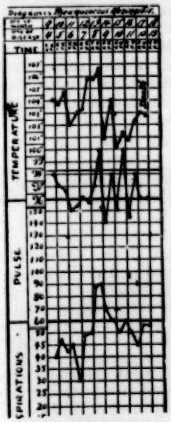

Fig. 4.

Symptoms of meningeal irritation are very common in the course of lobar penumonia in infancy and are in all probability due in most instances to the action of toxins and high temperature. In certain instances, however, there is bulging of the fontanelle, and lumbar puncture shows that there is an excess of cerebrospinal fluid under increased pressure. In these cases, however, the cerebrospinal fluid is clear, does not form a fibrin clot or contain an excess of cells or bacteria. The following case is an example.

A boy, eleven months old, was taken suddenly, on the sixth day of a lobar pneumonia, with tremor and delirium. The anterior fontanelle was bulging. There were clonic spasms of the extremities and retraction and rigidity of the neck. The pupils were equal and dilated, but reacted feebly to light. Lumbar puncture was done and 15 ccm. of clear fluid under much pressure were allowed to run off. This fluid did not contain a fibrin clot or an excess of cells, and cultures from it were negative. The fontanelle was bulging again within an hour after the puncture. The next day there was internal strabismus on both sides. The right pupil was much dilated; neither pupil reacted to light. The neck was rigid and there was moderate opisthotonos. There were constant clonic movements. The knee-jerks were much exaggerated. Kernig's sign could not be determined because of the rigidity. Another lumbar puncture was done and 60 ccm. of clear fluid, under very high pressure, were allowed to run off. This fluid did not deposit a fibrin clot or show an excess of cells, and cultures were negative. He went to sleep during the withdrawal of the fluid.

His condition remained essentially the same from this time until his death on the tenth day. The fluid obtained from lumbar puncture on the eighth day was also entirely normal. No autopsy was obtained.

This type fits in very well with what has been called serous meningitis and may be explained as being the result of excessive secretion from toxic irritation. Holt[3] has, however, recently described a case in which there were evidences of increased cerebral pressure and in which the fluid obtained by lumbar puncture was normal, which apparently recovered. The baby died seven weeks later of a second attack of pneumonia. The autopsy showed an old meningitis of the convexity from which a pure growth of pneumococcus was obtained. It is possible, therefore, that, on account of the tendency of pneumococcus meningitis to be localized at the convexity, more of the symptoms of meningeal irritation occurring in pneumonia may really be meningitis than we have in the past supposed.

*Influenza meningitis.* — The symptomatology of influenza meningitis in infancy is so similar to that of other forms of meningitis at this age that a diagnosis is impossible without lumbar puncture. In general, it resembles cerebrospinal more than tubercular meningitis. The blood does not show a leucocytosis. The cerebrospinal fluid, as in cerebrospinal meningitis, is very turbid or purulent and the cells are almost all polynuclear. It almost always contains a large number of influenza bacilli. The following case is an example of this form of meningitis.

A boy, nine months old, had always been well up to May 7, when he became feverish and coughed, and had much mucus in his throat. A physician who saw him at that time said that he had bronchopneumonia. He had several convulsions May 15, which were followed by marked rigidity and almost constant twitching. He became drowsy and refused to take his food. He did not vomit and was not constipated. He was admitted to the Infants' Hospital May 16.

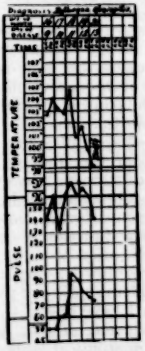

Fig. 5.

*Physical examination.* — He was well developed and nourished and of good color. The anterior fontanelle was 3 cm. in diameter and level. There was no rigidity of the neck. He was unconscious, but made frequent involuntary motions. The pupils were equal and reacted feebly to light. The heart, lungs, ears, throat and abdomen were normal. There was no paralysis,

[3] Am. Jour. Dis. Child., 1911, vol. i, p. 26.

but slight spasm of the extremities. The knee-jerks were not determined because of the continuous motion. Kernig's sign was absent.

The urine was clear, acid and contained no albumin.

Three cubic centimeters of very turbid fluid under low pressure were obtained by lumbar puncture. This fluid contained a large number of cells, 98% of which were polynuclear and 2% mononuclear, as well as very many bacteria which were later proved by Dr. Calvin Page to be influenza bacilli.

The twitching of the extremities continued, but he had no convulsions. There was never any rigidity of the neck, but there was moderate rigidity of the extremities. The knee-jerks were never determined because of the twitching. Kernig's sign was at times present on one side, but not on the other. The fontanelle remained depressed until the day before death. The pupils became widely dilated and did not react to light. He died, after progressive failure, May 20.

Influenza meningitis usually runs a short course and is almost invariably fatal. Treatment can be only symptomatic.

## COMPLETE RUPTURE OF THE SUPRASPINATUS TENDON. OPERATIVE TREATMENT WITH REPORT OF TWO SUCCESSFUL CASES.

BY E. A. CODMAN, M.D.,

*Assistant Visiting Surgeon, Massachusetts General Hospital.*

IN a paper on "Stiff and Painful Shoulders," published in the BOSTON MEDICAL AND SURGICAL JOURNAL for May 31, 1906, in speaking of rupture of the supraspinatus tendon in connection with subacromial bursitis, I presupposed, on anatomical grounds, the probable symptoms of such rupture as follows:

"One theoretical symptom (since the supraspinatus is put out of action) should be the persistence of passive and loss of active abduction. I am not ready to say this as yet, however, because in most cases the pain is so great that spasm prevents even passive motion, and later adhesion takes the place of spasm. When rupture of the tendon does take place, it probably is only partial and a Y-shaped attachment still remains to perform part of the function. (Fig.) In a similar way, the quadriceps may extend the femur when the patella is broken if the lateral expansions of its tendon are not torn. Nevertheless, I believe that the active function of the supraspinatus is important in elevation of the arm."

Since this paragraph was written I have had two cases of complete rupture of the supraspinatus tendon on which I have operated, and in both of which I was able not only to demonstrate the existence of the anatomical lesion in conjunction with the above symptoms, but succeeded by suturing the tendon to the tuberosity in bringing about complete restoration of the function of abduction. I have also, in a number of cases, verified the clinical diagnosis of a partial rupture such as depicted in the accompanying figure, which was produced in the other articles which I have written on this subject. (The reader is referred to the articles appearing in the BOSTON MEDICAL AND SURGICAL JOURNAL for Oct. 22 and 29, Nov. 5, 12, 19 and 26, and Dec. 3, 1908.)

This partial rupture is the common lesion, and, as I have explained, the remaining portion of the tendon is competent to take up the function when the sensitiveness due to the reparative process about the point of rupture has disappeared. The curious deposits of lime salts sometimes shown in the x-ray, and spoken of by Painter and Baer, are, I believe, faulty attempts at repair of these tiny ruptures of the tendon.

The following two cases are quite definite because they present complete rupture of the tendon of the supraspinatus. Therefore, the function of active abduction was almost entirely lost.

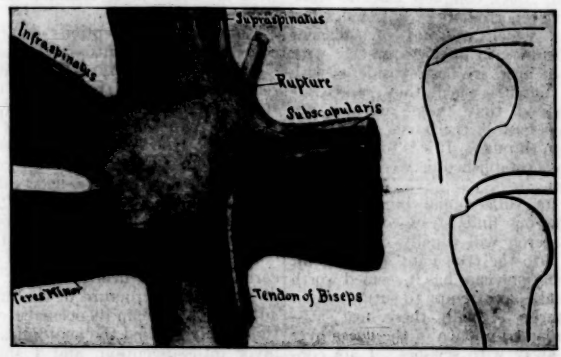
CASE 1. — Mrs. J. A. Aged fifty-two. Born in Scotland. Referred by Dr. Kent, of Dorchester, March 7, 1909.

Patient had always been a healthy, hard-working woman and had practically never been sick. On Oct. 3 of the previous year, i. e., five months before I saw her, while she was hanging recently washed clothes on the line in her yard, she endeavored to toss over a heavy blanket and felt something snap in her shoulder as she threw her arm up. She felt an intense pain and her arm fell and "hung by her side for a while." She was examined later by Dr. Kent, who found no thickening or ecchymosis. An x-ray was negative. Since then she had not been able to abduct the arm and had suffered much pain at night and somewhat during the day. The symptoms were in general those which I have described as the symptoms of adherent subacromial bursitis. The following points were, however, noticeably different.

(1) There was little atrophy of the deltoid, and it even appeared hypertrophied on account of the apparent swelling of the joint beneath. (2) Under the fibers of the deltoid, beneath the acromion and over the joint, there was a distinct deep fluctuation as if the whole bursa were full of fluid. (3) The ability to start abduction was absent, but when the arm was passively abducted to about 140°, the patient, by a strong contraction of the deltoid, could prevent the arm from falling for an instant, but the slightest downward pressure made it drop to the side. External rotation was about one half the normal.

*Operation.* — March 11, 1909. Usual incision between fibers of deltoid. Roof of bursa abnormally thick with granulation-like bodies on its under surface. Escape of straw-colored fluid, about one-half ounce. The floor of the bursa was found communicating with the joint, because practically the whole supraspinatus was torn from its insertion and retracted inwards. The biceps tendon was exposed over the articular surface, but was apparently uninjured. For about one-half inch on the lower visible portion it was bright pink; the rest of it was normal in appearance. By holding the bursa wide open, pulling down on the arm and raising the elbow from the table, the retracted end of the supraspinatus could be seen. This was caught with a tenaculum and pulled down enough to suture with four heavy silk threads to the remaining portion still attached to the tuberosity. This could not be done exactly, but was done nearly enough so that it seemed possible for repair to take place along the silk sutures. A little gap was also left on each side, which was not covered with tendon substances. It was in a sense a *suture à-distance*. When the operation was completed it seemed as if there was a fair possi-

bility of the supraspinatus obtaining enough attachment to enable it to perform its function, although the base of the bursa would necessarily remain a rough instead of a smooth surface. Dr. Kent gave ether, Dr. Vincent assisting. Dr. J. J. Putnam and Dr. M. P. Smithwick present.



June 9, 1909. Looks very strong and well. Sleeps well. Arm aches at times but not much. Pain in stormy weather (after use). Gets good use out of arm and does her own work. Can button back of dress and do her own hair. *Real* free abduction to 135°. Fair rotation. Muscles developing well and deltoid is strong. Very much pleased with result.

This patient was demonstrated to the Interurban Orthopedic Club, March 25, 1911. The arm is perfectly well and the function is perfect. The only abnormal sign is that the deltoid is unusually prominent due to the presence of joint fluid in the bursa.

Club invited to examine the case and witness the operation.

*Operation.* — Jan. 10, 1911, at the Massachusetts General Hospital.

As in the previous case, when the fibers of the deltoid and the thickened roof of the bursa were incised, there was an escape of straw-colored fluid and the bursa was found to be in communication with the true joint. The supraspinatus had retracted so far that at first it could not be seen, and one looked directly at the articular surface of the bone with the uninjured biceps tendon lying across it. With some difficulty the supraspinatus tendon was caught with a tenaculum, freed and pulled forward. It was then sutured "*à-distance*" to the tuberosity with heavy silk prepared with paraffine after the manner of Lange. As in the previous case, the retracted tendon could not be entirely united, but enough strands of silk were put in to make

Case 2. — Mr. D. R. Aged forty. Hostler. Referred by Dr. John Homans, Dec. 21, 1910.

Patient is a strong, wiry Irishman. He has always been well. About three and one-half months previously, he had been saddling a horse in the stable and while tightening the girth he felt something in his shoulder give way and he fell to the floor. There was immediate loss of power in the arm, but he managed to finish saddling the horse without raising that arm. That night he consulted Dr. Luce, of Canton, who found no ecchymosis, but thought there was slight crepitus. An x-ray a little later was negative. The hip was also hurt by his fall, so that for some time he was more bothered by that than he was by his shoulder and he was obliged to use crutches for several weeks. At the time he presented himself to me for examination the symptoms were at first sight those of the adherent type of subacromial busitis, but on more careful examination the same signs that were present in the previous case were demonstrable, that is, (1) Relatively slight atrophy of the deltoid and an appearance of hypertrophy. (2) Fluctuation over the region of the bursa beneath the deltoid producing a "*verwölbung*" of the latter. (3) The persistence of nearly normal passive abduction with no active abduction. When the arm was passively abducted, the patient by a strenuous exertion of the deltoid could hold the head of the bone on the glenoid and thus prevent the arm from falling immediately. (4) In this case a distinct depression could be felt just above the tuberosity at the point where the tendon was torn away from the latter. A definite diagnosis was made and the members of the Boston Orthopedic

it possible for the function of the tendon to be replaced.

Convalescence was normal and the patient was not allowed to use the arm in abduction for three weeks, but since then has been using it with more or less freedom. He was shown to the Interurban Orthopedic Club on March 25, and the following condition noted at that time:

Patient is working every day — can chop wood and do other "chores" without pain. He can easily place his hand on top of his head or behind his back. Full abduction of the humerus on the scapula is, however, weak, and although he can elevate his arm, he cannot hold it in an abducted position against a downward pull of even moderate force. The strength of the arm in other respects is excellent and the patient is well satisfied. The function of the supraspinatus is fully as good as it was in Case 1, at the same length of time after the operation.

I have seen only one other case in which I have made a diagnosis of complete rupture of the supraspinatus, and as I have not been able to persuade this patient to allow me to operate, his present condition is very instructive as compared to the two cases mentioned above.

In spite of the fact that the patient is a powerful man with an extremely well-developed deltoid, he is now, four years after the injury, still unable to start abduction. As in the other cases, however, when the arm is passively abducted so that the patient's deltoid acts in the same line of force as the axis of the humerus and the remaining short rotators (i. e., subscapularis, teres

minor, infraspinatus), the head of the humerus obtains a fairly firm contact with the glenoid so that the weight of the arm can be held by a great effort of will on the part of the patient. The slightest pull downward on the arm, however, will overcome what little power he has, and as soon as the fulcrum on the glenoid is lost, the arm drops to the side.

It will be necessary for those readers who are interested in this subject to refer to the articles mentioned above to thoroughly understand this one, but, best of all, they should look for themselves at dissecting-room subjects, because injuries to this tendon are so common that I have never had any difficulty in finding examples of it in a single set (20) of dissecting-room subjects.

The injury, as I have explained, is usually confined to a partial rupture of not more than ¼ to ½ inch in breadth. Such complete cases as these three which I have reported are exceptional. The smaller ruptures, which are not of sufficient mechanical importance to interfere greatly with the function of the arm, are best considered with the subacromial bursitis which they cause. It must be understood that these ruptures are beneath the serous base of the bursa, which may or may not be torn through. If it is torn through, a communication is established between the bursa and the true joint.

In operating for subacromial bursitis, if on entering the bursa one finds straw-colored joint-fluid, a careful search will usually demonstrate a small opening into the true joint at the point of rupture. In only one case has it seemed worth while to me to make an attempt to suture one of these small ruptures. Usually these heal satisfactorily if the inflamed portion of the bursa over them is clipped away with scissors. I am convinced, nevertheless, that suture is necessary in long-standing complete cases such as those cited above. The one which was not sutured has a decidedly impaired function and for two years was unable to work.

I have never seen the tendons of the other short rotators ruptured except in conjunction with that of the supraspinatus. Twice I have seen a longitudinal split between the tendon of subcapularis and that of the supraspinatus.

## INTUSSUSCEPTION IN CHILDREN.*

BY JAMES HERBERT YOUNG, M.D., NEWTON, MASS.

OF all the causes of intestinal obstruction at all ages, intussusception comprises one third, while in infants it comprises three fourths. Nevertheless, it is not a common disease. At the Children's Hospital in the five years from 1903 to 1908, there were but eight cases, and the same number at the Infants' Hospital in the ten years previous to 1908.[1] Out of about 1,200 permanent cases at the Boston Floating Hospital for the last three years, there has been but one case of intussusception.[2]

Holt,[3] in an analysis of 358 cases of intussusception in children under ten years of age, found that 75% occurred in the first two years of life and 50% between the fourth and ninth months. Hess[4] found practically the same percentage in 314 cases, namely, 60% between the third and twelfth months. The disease is three times as frequent in males as in females.

Invaginations of one part of the intestine into another may occur at any part of the intestinal tract from the duodenum to the rectum, but, as naturally would be expected, the junction of the large and small gut is the most common site. These invaginations are usually single, when section shows three intestinal layers, but may occasionally be double, when the intussusception consists of five layers, and very rarely triple, in which case there are seven layers. Clubbe's[5] experience has shown that double intussusceptions are much more common than has generally been supposed.

Enteric intussusceptions comprise 0.6% and colic 1.9% of all intussusceptions according to Clubbe's statistics in 157 operated cases. The remainder occur at the junction of the large and small intestine. It has been generally believed that the vast majority — 75 out of 90 cases according to Holt — were of the ileocecal type, but Clubbe found that only 29.4% of his cases were true ileocecal, the ceco-ileocecal variety being more common, 32%, while 27% were double intussusceptions involving the cecum. The ileocolic type occurred in 9.7% of the cases.

Considering the frequency of this disease in early life, it is natural to suspect that differences of anatomical structure in the infant and in the adult would explain its occurrence. Dunbar[6] has thoroughly studied the anatomical changes which favor intussusception, and I shall quote freely from his paper. In the first place, the mesentery is proportionately longer in infants, the intestinal walls are thinner and there is greater mobility of the cecum and ascending colon. Then there is the rapid growth of the intestine, which, according to physiologists, is always associated with more or less perversion of function. At birth, the large and small intestines are very nearly the same size. The small intestine, about six feet in length at birth, is ten feet in length at the end of the second month, with practically no change in caliber; while the large intestine does not increase at all in length during the first four months of life, but increases rapidly in diameter. The region of the cecum, the most frequent location of intussusception, shows the most marked anatomical change. During the first few months, owing to the small pelvis and to the relatively larger colon, there is no small intestine in the pelvis. About the fourth month, which is the time when intussusception usually begins to occur, the small intestine descends into the pelvis. The ileum, which before formed a right angle with the cecum, now forms an acute angle, bringing the long axes of the cecum and ileum more nearly parallel and thus facilitating invagination at this point. Then, too, it is normal in infants for the small intestine to project very slightly into the cecum, and so it may be said that in

* Read at the Surgical Fortnightly Club, March 7, 1911.

infants there is normally an incipient intussusception.

Given these anatomical changes, what are the disturbances of function which may produce intussusception? The perversion of function due to the rapid growth of the intestines has already been mentioned. The immediate predisposing cause is probably due to exaggerated peristalsis, which causes irregular action in the muscular wall of the intestine, and may be brought on by diarrhea, trauma or mechanical causes. Nothnagel,[7] in 1884, proved by animal experimentation that irregular action in the muscular walls of the intestine could produce intussusception. He found that vigorous stimulation of one part of the bowel produced an annular contraction, which contracted ring was drawn into the bowel above, and invagination started, always in the direction of the peristaltic wave. He saw, moreover, that this swallowing of the contracted ring was not due to the fact that it was pushed forward from behind, but to the fact that the relaxed segment above was drawn over the contracted one by action of the longitudinal fibers of the relaxed segment. Then the contracted ring or intussusceptum was forced onward, as any foreign body, by contraction of both circular and longitudinal fibers. The growth of the intussusception, however, was at the expense of the relaxed, receiving portion, the contracted portion always remaining the head of the intussusceptum. For example, if a portion of the jejunum is invaginated into the ileum, increase in length is at the expense of the ileum. In an ileocecal invagination, the ileocecal valve is first invaginated. The invagination may proceed so far that the head of the intussusceptum may project from the anus, but that head will be, as at the beginning, the ileocecal valve. The increase in length being at the expense of the ascending and transverse colon, examination would show no trace of the ascending or transverse colon, but would give the appearance of the small intestine entering the descending colon. No matter what segment of the bowel forms the original apex of the intussusceptum, that apex will remain the same even if the length be doubled or trebled.

Like all rules, this one has an exception, the ileocolic variety. In this type the ileum is forced through the ileocecal valve, and as the valve remains fixed, as long as the intussusception continues to grow, the apex of the intussusceptum is constantly changing. Another physiological cause not to be overlooked is the fact that the peristaltic waves of the ileum stop at the ileocecal valve, and new peristaltic waves in the colon start, thus favoring intussusception by having one part contracted while the other is relaxed. To make the etiological factors complete it is only necessary to mention such causes as tumors of the mesentery or intestine, foreign bodies in the intestine and invaginations of Meckel's diverticulum and of the appendix.

The pathology of the condition, after it has once formed, is similar to that of a strangulated hernia. The obstruction to the blood supply with its consequent congestion and edema, followed by inflammatory exudate, adhesions and possible gangrene, is familiar to all and needs no further mention here.

Given, then, an individual whose anatomical structure favors intussusception, with a rapidly growing intestine and its consequent perversion of function, what are the signs and symptoms by which the condition may be diagnosed when it occurs? Sudden, severe, intermittent abdominal pain is the first symptom. The infant almost invariably has been previously healthy and is often breast-fed, and if there has been some slight gastro-intestinal disturbance, the onset of a more serious condition is perfectly obvious. The attack may come while the child is nursing, or he may awake, screaming, from a peaceful sleep. The intervals between the attacks of pain may vary from a few minutes to an hour. Vomiting soon occurs and may be almost projectile in character. The vomitus consists of food and then bile-stained mucus, but it is rarely stercoraceous. If the mother is not alarmed by the colic and vomiting, the appearance of blood in the stools usually leads her to seek medical aid. With the onset of pain the child may have a normal movement, but usually four or five hours later, depending somewhat on the location of the intussusception and the state of congestion, blood and mucus or blood alone appear in the stool, with the entire absence of fecal material. The child at this time does not appear especially sick, has a normal temperature, and, if not seen in an attack, seems well and happy. This is the time, however, when the diagnosis should be made, and careful attention to the mother's history should make it possible. Examination may or may not show a tumor, but if no tumor is felt, and if the diagnosis cannot otherwise be made, examination under ether at this time is not only justifiable, but demanded. A tumor is felt in about 86% of the cases. It is usually of the characteristic sausage shape, but not necessarily so. A rectal examination should always be made, and often the apex of the intussusceptum can be felt.

The differential diagnosis practically narrows down to those diseases which show blood in the stools. Excluding local causes of bleeding and the hemorrhagic diseases, there is only infectious and fermental diarrhea left to consider. Both have temperature, which is absent in intussusception in the early stages; neither has colicky pain, and the stools always shown fecal matter mixed with the blood and mucus. Appendicitis may show the presence of a tumor, but it is usually less distinct and not movable, as is the tumor in intussusception, and there is fever, leucocytosis and the absence of blood in the stools. Of the other causes of intestinal obstruction, nothing need be said; treatment is the same.

Although in speaking of the treatment of intussusception, I am entering the province of the next paper, I want to say a word in regard to this phase of the subject from a medical point of view. In speaking of the treatment, I shall

not refer to what *can* be done, but to what *should* be done. Ten or fifteen years ago a discussion of the treatment from a medical and a surgical standpoint would have been spirited, the medical man defending enemata and inflation of the colon, the surgeon laparotomy. To-day, however, such a discussion would be impossible as the best medical authorities are convinced that the treatment of intussusception is immediate laparotomy. That there are men still unconvinced is true, but it cannot be long before the brilliant results of surgery will have converted every one, and surgical interference will be the first thought in intussusception as it now is in appendicitis. The surgeons must not criticise too harshly, but must realize that medical men have only to pass through those stages which they themselves have passed. The surgeon has not always been ready to operate early.

As examples of the modern medical point of view I will quote briefly from three recent books. Kerley,[8] in his last edition of "Treatment of the Diseases of Children," says, "Intussusception is such a distinctly surgical affection that, like appendicitis, it requires but little notice here." "It is my custom in such cases first, to send for the surgeon and then make one attempt at reduction by water pressure." Koplik [9] says: "The diagnosis of intussusception once made, the case is one for surgical interference. The sooner surgical treatment is begun, the better the chances of recovery." Morse [10] is even more emphatic. He says: "The only rational treatment for intussusception at any stage is immediate operation as soon as the diagnosis is made. Attempts at reduction by inflation of the bowel with water or air are in rare instances successful. In the vast majority of cases, however, they are unsuccessful, they waste time and use up the child's vitality. It is impossible, moreover, to know at once whether the intussusception has been reduced or not by these measures, so that on this account more time is wasted."

Although the treatment is surgical, the physician must shoulder the responsibility of the high mortality. Clubbe's mortality has fallen from 50% in the first 50 cases operated upon to 7% in the last 57 cases, due, he says, to the fact that physicians in his vicinity have been educated to recognize the condition enabling him to operate early. Thus it becomes the duty of the physician to make the diagnosis of intussusception at the very onset, and when the diagnosis is once made, to put the case immediately in the hands of a surgeon.

## TREATMENT OF INTUSSUSCEPTION IN CHILDREN.*

BY W. E. LADD, M.D., BOSTON, MASS.

STATISTICS are very apt to be misleading, and I believe that on intussusception they are more misleading than on many other diseases. However, I have compiled a few from the literature of the past ten years which may be taken for what they are worth, and are at least suggestive. The mortality of intussusception untreated is estimated at between 90% and 100%. That is, occasionally there is a case of spontaneous reduction, and rarely — but very rarely — a patient in whom the invaginated portion of gut sloughs off leaving the lumen patent. These cases are exceedingly rare and the probability is that if patients with intussusception were left untreated, the mortality would be nearer 100% than 90%. Now let us consider how much improvement over the above we may expect from irrigation, inflation and enemata of various forms. I collected from the literature 216 cases in which these various forms of treatment were tried. Out of this number, 40 recovered without further treatment; of the remaining number, every patient who was not operated upon died. This would suggest a mortality of about 81% for the non-surgical treatment of intussusception. Even this may be high, as it is possible that some of the patients with whom irrigation failed, and who were operated upon later, might have recovered through sloughing of the bowel or late spontaneous reduction. But it does not seem logical to expect much better than 70% or 75% mortality from the treatment by irrigation alone.

From the literature I also collected the operative results obtained by various surgeons in a series of 177 cases. Of these 54 were fatal, showing a mortality of 31 and a fraction per cent, and in several instances resection had to be performed. Omitting these cases, the mortality percentage would drop considerably. Resection, especially in infants with intussusception, is an exceedingly fatal procedure and should not, and would not, have to be resorted to nearly so frequently if the treatment recommended in various medical textbooks was not so carefully adhered to. The other factor in the still high mortality is *late operation*, which we likewise find recommended in some textbooks. Thus, in Rotch's [1] "Pediatrics" the following treatment is recommended: Food and cathartics are contra-indicated; hydrostatic pressure should be tried in the early hours of the attack, at first without ether, then with ether, then call a surgeon. He cites a case in which an infant six months old showed evidence of abdominal pains and passed blood by rectum one morning. That evening the physical examination was negative. The infant passed a restless night, occasionally vomiting, and next day a tumor appeared under the left costal border. Hydrostatic pressure was used unsuccessfully. A surgeon saw the patient and recommended waiting twenty-four hours, at the end of which

*Read at the Surgical Fortnightly Club, March 7, 1911.

time the patient was dead. The post-mortem examination showed the cause of death to be intussusception with a partial volvulus.

Osler [2] states that the treatment of intussusception should be by inflation or enemata, and that if this is not successful by the third day, surgical aid should be resorted to. No longer ago than February, 1910, at a meeting of the New England Pediatric Society, one of the men discussing a paper on intussusception recommended the use of injection and waiting until the tumor could be demonstrated and until it was proved that pressure would not reduce it. At a meeting of the British Medical Association in 1901, Dr. Turner stated that he had used irrigation in nine cases, in eight of which it had proved successful. So far as I can ascertain, this gentleman's experience is unique. At this meeting, Messrs. D'Arcy, Power, Eccles, Tubby, Abbot, Bush and Eve all favored laparotomy as soon as the diagnosis and necessary preparations could be made. Any teaching advocating prolonged use of irrigation or delay before operation is at variance with the opinions of most surgeons of to-day and in the writer's judgment is responsible in part for the still somewhat high mortality of laparotomy for the reduction of intussusception.

Irrigation, however, is still employed by many, not as an alternative for operation, but as an aid to it. Clubbe [9] uses injections of warm oil as a routine measure, to be followed promptly by operation if it is not successful. In his series of 138 cases, it has been successful fourteen times. This is not a large percentage of successes, about 10%, but still large enough to make it seem worth while trying. In his latest article, however, Clubbe [11] states that he has largely given up the use of irrigation. He reports his last 26 cases without a death and believes his good results to be due to having educated the general medical practitioner to make early diagnoses and to appreciate the value of immediate operation. Brewer [3] says the treatment of intussusception should invariably be surgical, but recommends, as does Clubbe, that distention of the colon with gas or water should be tried while the patient is being prepared for operation. Prolonged attempts at reduction by distention he says should be discouraged because they are weakening to the patient and render him less able to stand operation. Mr. Pitts reserves the use of irrigation for cases seen within a few hours of the onset of symptoms and as a preliminary to operation in other cases.

Wallis,[6] on the other hand, is opposed to the use of distention at any time. He considers that it results in the loss of valuable time, the loss of vitality, the possible rupture of the bowel and starvation of the patient, which is a very potent factor in infants; he also considers that it is rarely successful. He reports four successful operations and emphasizes rapidity of operation as an important element of success. His four operations occupied nine, ten, twelve and fifteen minutes respectively. Jacobson [4] holds the same view as Wallis with regard to irrigation, namely, that it should never be employed. He states that its dangers and the increased distention of the abdomen are a greater detriment than the partial reduction, sometimes accomplished, is a benefit. He advocates always operating as soon as proper preparations can be made and believes, as does Wallis, that speed of operation is a large factor in obtaining good results. Rigby [7] expresses similar opinions with the last two surgeons and reports five successful cases, in no one of which did the operation last more than fifteen minutes. My own experience has tallied with that of these surgeons. Two patients on whom I operated, one an infant two months old, the other four months old, both presented intussusceptions of the ileocecal variety, and in both instances the ileum was carried around from the cecum to the sigmoid. The baby two months old showed also a volvulus of the ileum. The operations took ten and twelve minutes, respectively, and both patients recovered. Erdman [10] takes a position between the views of the anti- and pro-irrigation men and reports a case in which enema was given and the tumor and symptoms disappeared. He, however, realizing the possibility of partial reduction having taken place, did an exploratory laparotomy and found three inches of the ileum still invaginated into the cecum; yet he recommends enemata as an aid to operation and to be tried in the first six hours with the hope of reduction if the surgeon will be prepared to operate at once on return of symptoms and will be ready to operate until the patient has had normal bowel movements.

As to the technic of distention, most writers are agreed that it should be given with the patient anesthetized and prepared for operation in case of failure. The patient should be on the table with the buttocks slightly elevated and the fluid introduced into the rectum through a nozzle or catheter by means of a hand or fountain syringe with about four feet of pressure. The buttocks should be held together firmly to aid in retaining the fluid. As to the kind of fluid used, Clubbe always uses warm oil; other men use warm salt solution. I cannot see that it makes a great deal of difference what fluid is used, but inflation with air has obvious disadvantages. While the injection is being given, manipulation of the mass through the abdominal wall may be of assistance sometimes. In case there is any tumor left after the injection, or in case of doubt, it is far safer to resort to operation at once than to wait.

As to the technic of operation, it is of great importance to keep children, and especially very young children, warm. The practice of bandaging the legs and arms and chest with wadding is a great aid in this respect and should never be omitted. The question of where to make the incision is of some importance. Brewer recommends making it over the tumor when localizing signs are present. Clubbe and Jacobson advocate the right rectus incision in many cases. Most of the other surgeons use a median incision, and this certainly has many advantages. It is quicker, there is less bleeding, and any part of the abdomen,

especially of a child, is easily accessible from it. Some surgeons only make a small incision first and endeavor to reduce the intussusception within the abdomen. Wallis and Clubbe are strongly opposed to wasting time in the endeavor to do this. I can imagine that some men might be very proficient in accomplishing this, but I feel sure that those whom I have seen try it wasted a great deal of time, and that in the hands of the majority of surgeons it is far wiser to deliver the mass through the wound as quickly as possible and commence reduction. The first part of the reduction is usually easy and may sometimes be accomplished by holding the gut firmly with one hand just below the advancing point and then sliding the thumb and forefinger of the other hand along the sheath, pushing the intussusceptum in front, much as one would empty a flexible rubber tube of air. The last few inches of the reduction are often difficult, and it is here that the operator must remember that it is unsafe to put much traction on the gut. The cause of the difficulty is usually edema of the gut and mesentery, which is a good point to remember, because steady pressure will frequently diminish the edema enough to allow a reduction which at first seemed impossible. It is always well to be persevering in attempts at reduction, as the mortality of resection is exceedingly high. When, however, resection becomes necessary on account of reduction being impossible, or on account of the existence of gangrene, there are three methods to choose from: End-to-end anastomosis with suture (or Murphy button); lateral anastomosis; and the method described by Mr. Jesset, which consists in uniting with a continuous suture the two portions of bowel at the point where the intussuscipiens receives the intussusceptum; then making a longitudinal incision in the free border of the intussuscipiens and delivering and excising the intussusceptum; suturing and replacing the stump. The longitudinal incision in the sheath is then closed. This accomplishes the same results as nature with her occasional spontaneous cure by sloughing. The rules for closing the abdomen are the same as in any surgical operation: close by layers if the condition of the patient warrants it, otherwise by through-and-through sutures.

The after-care of these cases consists in combatting shock and restoring vitality as quickly as possible. Wallis, Clubbe and Rigby recommend rectal saline infusions as soon as the child is put to bed, and strychnia or brandy given subcutaneously as a stimulant. They all agree that feeding should be begun as soon as possible and that in cases of nursing babies there are no ill-effects from giving the baby the breast early. Enemata are used in the first twenty-four hours to move the bowels and for two or three days afterward. Jacobson advocates the use of aseptic ergot subcutaneously, together with warm saline infusions to combat shock. In the first two or three days following an operation for intussusception there is likely to be considerable elevation of temperature, which Clubbe believes to be due to absorption from the bowel of toxins from retained blood clot, feces, etc. Whatever the cause of the temperature, it does not signify a peritonitis and, as a rule, comes to normal the third or fourth day.

From the review of this literature one seems warranted in drawing the following conclusions:

1. That intussusception is a very fatal disease.
2. That the mortality of irrigation and palliative treatment is high (about 70% at least).
3. That the mortality of surgical treatment is about 50% better than that of irrigation.
4. That the way to reduce the still high operative mortality is to operate early and not after exhausting the patient by attempted palliation and delay but as soon as the diagnosis is made.

## Clinical Department.

### A CASE OF PROGRESSIVE MUSCULAR ATROPHY CHARCOT-MARIE-TOOTH TYPE.

BY FREDERIC J. FARNELL, M.D., PROVIDENCE, R. I.

THIS form of muscular atrophy was recognized as a distinct type by Charcot and Marie [1] in February, 1886, and, quite independently, at almost the same time, by Tooth,[2] who wrote a thesis at Cambridge, England, under the title of "Peroneal Type of Progressive Muscular Atrophy," because, although it might attack any given group of lower leg muscles, it usually seemed to commence in the peroneal group more often than any other.

In 1889 Hoffman,[3] in Germany, published an article entitled "Ueber progressive Neurotische Muskel-Atrophie," which established a hitherto opposed new type of atrophy.

Sachs,[4] in 1890, published a paper on the "Peroneal Form or Leg Type of Progressive Muscular Atrophy," in which he described clearly the clinical picture in two cases and referred to two other such cases.

In 1899 Sainton [5] published, in Paris, a thesis into which he had gathered all cases up to that time reported, and published an additional case with autopsy findings. He described the Charcot-Marie type as commonly hereditary and often familial, although occasionally it occurred in isolated cases. It is seen more frequently in men than in women. Usually it develops first in the lower extremities, sometimes in the upper and occasionally in all four at once. In the lower extremities the atrophy does not extend above the lower third of the thigh, and in the upper extremities above the proximal portion of the

forearm. The atrophy and paralysis advance parallel with each other. The hand frequently presents the "claw" type, while there are special deformities in the feet due to the development of the paralytic clubfoot and an aspastic weakening. Disturbances in sensibility are common but not constant. Fibrillary tremors are almost invariably noted. Knee-jerks are reduced or abolished, very exceptionally increased. Changes in the electrical response are both quantitative and qualitative and vary from slight reduction to complete absence and occasionally show a partial or complete reaction of degeneration.

The nerves in the affected portions show a progressive interstitial neuritis. The lesion was not confined to the periphery in two of his cases, but the columns of Burdach were degenerated without the involvement of Lissauer's zone. The pyramidal tracts as well as the anterior horn cells and Clarke's column were also involved in the degenerative process. In his own cases the changes in the peripheral nerves were very slight, while the cases of Marinesco,[6] Virchow,[7] Freidreich [8] and Oppenheim [9] showed extensive neuritic changes. It should be added that in unusual cases the facial, ocular, faucial and laryngeal muscles have been affected, and in several cases the atrophy has progressed to the involvement of the skeletal muscles. There is rarely an optic atrophy.

Since the appearance of Sainton's paper a great number of additional facts have been ascertained and the possibility suggested that this type of atrophy may constitute the link between the myopathies and the spinal atrophies.

However, some conclusion as to the hereditary character of the disease has been raised, and Ausbach [10] has questioned whether it is hereditary in any way whatever, whereas Warrington,[11] Sachs, Osler,[12] Brasch,[13] Fabrian [14] and Church [15] have reported cases in which the hereditary taint was pronounced and extended back several generations. In the case reported by Church a notable existence of heredity was evinced and it appears that the disease had passed through five successive generations at least. This latter case resembles in many respects the report which follows.

Case. — Aged forty-six; Ireland; widow; temperate.

*Family history.* — Negative for both hereditary and familial disease.

*Personal history.* — There was nothing of interest regarding her early life. She married at the age of twenty-six a blacksmith of intemperate habits, who died three years ago of pulmonary tuberculosis. She had seven children, five of which are alive and well; she had no miscarriages. Syphilis was denied by the patient.

She has had three distinct attacks of manic-depressive insanity, manic phase, within the last seven years, each of about three months' duration and ending in complete recovery.

In March, 1907, she received a small lacerated wound of the right thumb with splitting of the nail due to an injury on a lead washboard. She treated herself with household remedies and removed the bandage after three days. There was no secondary infection. The following July she was operated upon for retroflexion of the uterus and laceration of the perineum, making an uneventful recovery. After leaving the hospital she noticed that she could not use her hands as well as previously, especially the right hand, which was numb and stiff. Four months later a double wrist drop was quite evident, and at the same time she complained of contraction and stiffening of the fingers and, as she expressed it, "lumps came on my wrists." She also had some pain in her arms and she was unable to hold objects in her hands. She went to a neurological clinic in New York City, where a diagnosis of "lead poisoning with neuritis" was made. A few months later she noticed that her gait was stiff and that she was unable to stand on her heels.

*Physical examination* (May, 1909). — No cranial nerve involvement. Pupils equal and regular in outline, reacted to light and accommodation within normal limits. No nystagmus or diplopia. There was a marked weakness in her hand grips. Her forearm and hands showed poor amount of muscular and adipose tissue. The thenar and hyperthenar eminences were thinned, and a marked atrophy of the interossei muscles was evident. She could not abduct or flex either thumb, and was unable to abduct the forefingers. There was a contraction of the second phalan-

geal joint in all fingers, more marked in the small fingers. She could not spread out her fingers. The attitude of the hands was ulnar deviation of the wrist and a typical "main en griffe." Flexion was better than extension at the wrist. Fair preservation of strength in the flexors and extensors of the arm, and no involvement of the upper arm or shoulder girdle. There was no apparent atrophy of the lower extremities, but she claimed that her legs were much thinner than formerly and there was some suggestion of a spindle shape. There was well-marked loss of strength in both flexors and extensors, — she was unable to raise her toes from the floor and she was unable to stand on her toes. Reflexes of the upper extremities were all absent with the exception of the biceps, which was well preserved. The knee-jerks were greatly diminished; the Achilles jerks were absent. No ankle clonus and there was no Babinski, Oppenheim or Gordon. Abdominal and cilio-spinal reflexes were present. Muscle sense was intact and there was no hypotonia. There was slight swaying in the Romberg position and she was able to stand better with her feet apart. Her gait was unsteady, of the steppage type, raising her feet high in the air and coming down toes first. On turning quickly she was liable to lose her balance. No sensory anomalies. There were fibrillary twitchings of the muscles of the thenar and hyperthenar eminences and also a sudden

muscular contraction with a tendency to clonicity, followed by a muscular quivering. No speech defect. Her lungs showed a suspicious process in the right upper lobe, but there was no disease of her abdominal viscera. Her urine was negative.

The electrical irritability of the muscles of her forearms, hands, legs, feet was markedly lessened to both galvanic and faradic currents. With the faradic current there was only a very slight contraction with fifty cells in the muscles of the upper extremities, whereas in the lower extremities it required a still stronger current. With the galvanic current, the right upper extremity showed KCC greater than ACC with the largest current, and the left upper extremity showed KCC equal to ACC with the largest current.

During the last one and a half years there has been little change in her condition, although upon one or two occasions Dr. J. W. Moore, of Central Islip, has found diminished sensibility to heat and cold, with preservation of pain and touch in both legs and hands. She has been examined from time to time since that observation was made, but the writer has been unable to corroborate those findings and when last examined there were no disturbances in cutaneous sensibility. The electrical examinations still show the same reactions to both galvanic and faradic currents, — a quantitative as well as a qualitative loss.

A cytological examination of the spinal fluid by Dr. Moore showed a moderate increase in lymphocytes, about twenty to an oil immersion field, and the Noguchi modification of the Wassermann reaction was considered positive in the fluid. The blood serum was not examined for complement fixation.

To sum up briefly: It is evident that the patient's first symptom of a neurological disorder occurred in 1907 with stiffness and numbness in her hands followed four months later by the development of a typical "main en griffe." In less than a year her gait became that of the steppage type. During the ensuing three years atrophy of the proximal portion of the forearms and hands and the lower third of her legs, assuming the spindle shape, has been evidenced. Fibrillary tremors, reduction in reflexes and both quantitative and qualitative changes in the electrical response have been manifested.

The clinical features appear to classify this case with the neuritic forms of muscular atrophies, it being atypical only in the fact that it has occurred as an isolated case; also that the onset began in the fourth decade of life, showing itself first in the upper extremities, but soon followed by difficulty in walking. Aside from this the course of the disease appears to be quite typical.

I am indebted to the kindness of Prof. C. L. Dana for the opportunity of reporting this case; to Dr. R. Foster Kennedy for his valuable assistance in my study, and to Dr. Wm. Mabon and Dr. G. H. Kirby for the privilege of viewing their records.

## HEMORRHAGIC DISEASE OF THE NEWBORN; REPORT OF TWO CASES IN ONE FAMILY.

BY ORION V. WELLS, M.D., WESTFORD, MASS.

INSOMUCH as in the analysis of a series of cases of hemorrhagic disease of the newborn, made by Doctors Green and Swift, in a recent issue of this JOURNAL (March 30, 1911), the condition was never found to occur in two babies of the same mother, I believe the two following cases should be of interest:

CASE I. Boy, born March 16, 1908, of a primiparous mother, after a labor of two hours.

Father and mother were in good health. Mother said she had always had a tendency to bleed profusely from any slight injury.

Baby was apparently normal and well at birth. When twelve hours old, without cause, it began to have epistaxis, hemorrhage into right scrotum, filling it, tense and shiny, to the size of a large walnut; hematoma of right groin 1 by 2 inches. It voided no urine, but passed meconium, normal in appearance. There was no bleeding from the umbilicus. Epistaxis continued twelve hours, when baby died.

CASE II. E. H., sister of Case I, born March 8, 1909, one year, lacking a few days, after Case I. The duration of labor was two hours and was normal.

Upon examination baby was perfectly normal, and functions were normal.

When thirty-seven hours old, while at mother's breast, its face was found to be covered with blood which flowed from a pinpoint abrasion on the bridge of the nose. Cause of abrasion unknown. The hemorrhage continued two hours, soon after which baby was seen by me.

*Examination.* — Looks well. Skin red; no icterus. Temperature, 99.6. There is a crust the size of a pinhead on the nose. Entire hard palate ecchymotic and three ecchymotic spots the size of a pea on the soft palate; profuse hemorrhage from umbilicus saturating the dressings, which, the nurse declares, were not stained four hours before; a hematoma the size of a cent on the angle of right scapula; no macroscopic blood in urine or stools.

*Treatment.* — Eight cubic centimeters fresh rabbit's serum were given as soon as possible. When baby was next seen, twelve hours after the first dose, there had been no further hemorrhage from the above places, but there had been a slight epistaxis from left nostril. Rabbit's serum, 8 ccm., was repeated and after this no more bleeding occurred. The serum was repeated again in twelve hours. The child is now over two years old and perfectly well.

The mother has borne one child since, which showed no tendency to hemorrhage.

THE State Board of Health announces that Senate Bill No. 140, to regulate the practice of optometry in the State of Illinois, was defeated in the Senate, May 3, by a vote of 14 to 10. Eighteen more senators were present but did not vote, To pass a bill, twenty-six votes are required. — *Jour. Am. Med. Asso.*

# Reports of Societies.

## MEDICAL SOCIETY OF THE STATE OF NEW YORK.

One Hundred and Fifth Annual Meeting, Held in Albany, April 16, 17 and 18, 1911.

*Monday, April 16.*

MEETING OF THE HOUSE OF DELEGATES.

The usual reports of officers and committees were presented. That of the Secretary showed that, during 1910, 477 new members were received, and that on Jan. 1, the membership was 6,681. He stated that the experience of five years since amalgamation (with the New York State Medical Association) had shown that each year the society is gaining, not only numerically, but in importance and influence. The Committee on Experimental Medicine in its report referred to its successful efforts, in co-operation with the Committee on Legislation, in preventing the passage by the Legislature in 1910 of two anti-vivisection bills, and spoke of the necessity in the future of unceasing vigilance in this contest with prejudice and unreason. In his report of malpractice defense for the year, the counsel of the society, Mr. J. T. Lewis, said: "It will be gratifying to the members to know that the malpractice defense initiated in this state is daily gaining in national importance. Sister societies of various states are becoming imbued with the determined fight made against blackmail here, and the medical profession is fast coming to realize how important it is that its members throughout the country should stand shoulder to shoulder in repelling an attack than which there is no litigation more vicious and far-reaching in its importance, not only in its effect upon the profession, but also by its indirect influence upon the public health." Having given a synopsis of the new cases begun during 1910, he said: "In the above list of cases it will be noted that a large percentage of them have women plaintiffs. The only explanation is that the attorneys bringing these actions are inspired with the hope of enlisting the sympathies of a jury. Formerly a great majority of the cases were based upon alleged improper treatment of fractures, but it is evident that, discouraged in that field, attorneys have hope in this new one."

*Tuesday, April 17.*

PRESIDENT'S ADDRESS.

The address of the President, Dr. Charles Stover, of Amsterdam, was devoted to the general subject of medical education. In the course of it he suggested that a satisfactory history of medicine would be of material service to the student.

STUDIES ON A LOCAL HEMATOLOGICAL FACTOR IN THE CAUSATION OF UTERINE HEMORRHAGE.

By Dr. A. Stumdorf, Manhattan. He spoke first of hemorrhage from systemic causes, circulatory and hemic, and of hemorrhage accompanying demonstrable uterine, adnexal and pelvic disorders; after which he proceeded to treat of hemorrhage occurring in the absence of demonstrable systemic or local derangements. The results of his studies were summarized as follows: (1) The general circulating blood during the menstrual period and in the hemorrhagic conditions here considered shows normal coagulative properties. (2) During menstruation and hemorrhage the endometrium receives normally coagulable blood, but gives vent to this blood in a non-coagulable state. (3) The non-coagulability in the menstrual and hemorrhagic blood displays an identity in experimental and clinical manifestations differing only in degree. (4) Under the given conditions the endometrium exercises a function capable of rendering coagulable blood non-coagulable. (5) This function is due to the presence of an inhibiting substance generated *in loco*, and not the result of a dialytic process, as suggested by Cristae and Denk. (6) The non-coagulable blood contains all the essentials for coagulation; nevertheless, this blood is capable of inhibiting coagulation in normal blood from the same individual. (7) All of which tends to warrant the assumption that an inhibitive element as regards coagulation, probably augmented in activity by contributory structural abnormalities, presents a local causative factor in the production of uterine hemorrhage.

OPERATION FOR ADHERENT RETRODISPLACED UTERI BY SHORTENING THE ROUND LIGAMENTS THROUGH THE INGUINAL CANAL, AFTER ABDOMINAL SECTION THROUGH THE TRANSVERSE INCISION.

By Dr. LeRoy Broun, Manhattan. He considered this method of restoring and retaining the uterus in its forward position ideal in that, first, the procedure is anatomical, no abnormal implantations of the uterine supports being made or false adhesions brought about; second, the strongest part of the round ligament is utilized.

DIAGNOSIS AND SURGICAL INDICATIONS OF DUODENAL ULCER.

By Dr. James T. Pilcher, Brooklyn. Having stated that in some instances it is practically impossible to differentiate this from uncomplicated ulcer of the gastric outlet, he said the purest type of symptom-complex is evidenced by duodenal ulcer. This was characterized by four cardinal symptoms: chronicity, periodical exacerbations, peculiar pain, and the relief of pain by the ingestion of food or alkalies. The correctness of these diagnostic signs was demonstrated by the analysis of 156 cases personally investigated. While the results of analysis of the gastric contents, which was made in every instance, were not diagnostic, these not infrequently furnished confirmatory evidence. The same might be said of the duodenal bucket, which was employed in 25 cases, and certain inferences could also be derived from the thread impregnation test and x-ray pictures. The existence of latent cases was not to be overlooked. There was no ground, he said, for conflict between physician and surgeon in this field. The conditions calling for operative interference were hemorrhage, stenosis, tumor and intractability. The cases operated upon had been treated medically for an average of twelve and one-half years without any permanent relief, and he pointed out that the small operative mortality in duodenal ulcer was more than offset by the enormous percentage of deaths in cases where perforation occurred.

THE TREATMENT OF BLADDER PAPILLOMATA WITH THE HIGH-FREQUENCY CURRENT OF OUDIN.

By Dr. Edwin Beer, Manhattan. It was well known, he said, that these growths are difficult to cure and that they simulate malignant growths almost regularly. Guyon taught that they were clinically malign, and Rokitansky called them carcinoma villosum. These papillomata had been attacked by suprapubic cystotomy with very unsatisfactory end results, since, as a rule, they recurred. Of late they had been attacked transperitoneally, with the removal of the growth together with the whole thickness of the bladder wall, but it was difficult to believe that by this method

recurrences were going to be less frequent than by the older transvesical procedure. The third method was introduced by Nitze, who used the operating cystoscope, snaring the growth and cauterizing the base. This gave the best results up to date. The fourth method, introduced by the speaker, made use of the transurethral route, and consisted in the destruction of the growth by direct application of the Oudin high-frequency current to the neoplasm. The technic was simple and the procedure painless, and up to the present the results had been most satisfactory, not only in his own hands, but in those of several other operators. In all, thirty-seven separate tumors had been treated and destroyed. Two of Dr. Beer's cases had remained well the greater part of a year and continued so, without any sign of recurrence, and similar experiences had been met with by the other surgeons. It would appear, therefore, that this simple method of treating bladder papillomata will be the method of the future.

### THE NEW OPERATING PAVILION FOR THORACIC SURGERY AT THE GERMAN HOSPITAL, NEW YORK.

By DR. WILLY MEYER, Manhattan. Upon his return from the meeting of the American Medical Association in 1908, where thoracic surgery had been a topic of discussion, Dr. Meyer induced the trustees of the hospital to open it to this new branch of surgery. A machine shop in the building was fitted up as an operating room, and one of his positive differential pressure cabinets installed. In 1909 and 1910 several thoracic operations were performed, and the experience gained showed that more room was needed and that it was advisable to establish a separate department for thoracic surgery. Funds were collected for the purpose, and the building and plant have now been completed and turned over to the hospital. The equipment consists of one universal chamber which is a combination of a negative chamber with a positive differential pressure cabient within the same, and is located in the aseptic operating room, and one positive differential pressure cabinet in the septic operating room. Having described the equipment of the power room, he went on to say that the whole installation of light and power has been cut up into small units, and each individual circuit is separately protected, so that the chamber can never be without light or power, and the complete interruption of an operation is excluded. The beds in the recovery rooms have been constructed on the lines of a stretcher; they have no head-frame and are of such a height that the patient can be wheeled to the apparatus on the bed, and can be placed under differential pressure without being taken from it. This has been done because the procedure may not have been finished with the surgical interference, but may extend over the first twenty-four or forty-eight hours of the after-treatment. As speedily as can be, the new department will be placed on the broadest possible basis and will be equipped with every known useful type of apparatus for thoracic surgery; so that it will be possible to individualize and to employ in every instance the apparatus appropriate to the case in hand, as well as to make observations, for the scientific elucidation of such cases, by co-operation with specialists in allied branches.

### THE BLADDER AND THE PROSTATE.

By DR. J. F. W. WHITBECK, Rochester. It was not his purpose, he said, to attempt to present a scientific or novel paper for the expert, but rather a practical view of the subject for the consideration of the general practitioner. It had been estimated that at least one third of all men have an enlargement of the prostate which involves the bladder in difficulties. The residual urine, after micturition, might be sufficient to so paralyze the bladder as to cause retention which might require the use of the catheter. With even a moderate residual urine there might result decomposition or the deposit of a sediment from which a calculus could be formed. In order to prevent increased prostatic congestion and vesical irritation it was important to regulate the diet so as to have the urine as bland as possible, and the time and frequency of urination, to preserve the capacity and contractility of the bladder. The patient should also be instructed to be deliberate in urinating in order to expel as much as possible of the residuary urine. Water was the best diuretic, and would do more to render the urine bland than any other agent. The risks of catheterism could not be over-estimated. When this was required the anterior urethra should be cleansed by syringing with a 1 to 10,000 bichloride solution, and the glans penis and the meatus should also be sponged with it. The catheter, having first been boiled (preferably in a solution of boric acid), should be lubricated with some aseptic material, and the hands of the operator should be surgically clean. A soft rubber No. 8 catheter was recommended, and a convenient lubricant might be composed of one part adrenalin solution, one part 4% solution of cocaine in 1 to 5,000 bichloride, and four parts some such aseptic lubricant as was furnished in tubes by the chemist. The metallic catheter should not be employed if a soft rubber catheter could be passed, and No. 8 appeared to be better than a larger size. The speaker would not recommend the use of the sound in prostatic disease, nor would he advise castration for the cure of this affection. Experience showed that in a patient in fair health the prostate might be removed without difficulty or danger. There were dangers in delay, and a limit to the time when this operation could be done safely, for cystitis, pyelitis, calculus and other serious conditions might follow the continued use of the catheter and the indefinite postponement of radical treatment.

## SYMPOSIUM ON SALVARSAN.

### THE SIGNIFICANCE OF SALVARSAN AND ITS PLACE IN THERAPEUTICS.

DR. S. J. MELTZER, Manhattan, said that therapeutics, which ought to be the most important part of medicine, had been neglected during the new era in scientific medicine, and a fatal conviction became rooted that the cause of disease cannot be reached by any therapy. Two therapeutic methods, however, had been developed during this new era, one to treat symptoms and the other to strengthen the patient by physiological measures. The study of immunity brought to light a method of treatment aiming at the cause of the disease, consisting in utilizing the means of the animal organism which it employs when it recovers from an infectious disease. These means were the antitoxins, of which at least two were of practical value: those of diphtheria and meningitis. The method, however, had its limitations. The two old drugs which were real specifics against the cause of disease, mercury and quinine, were accidental remedies, with the discovery of which neither science nor art had anything to do. Salvarsan was a specific for several diseases which are caused by a closely related group of parasites, the spirilla; it was a spirillocide. It was a synthetical chemical compound, made with great ingenuity to fit, in the first place, just the group of spirilla. It was based upon such simple principles as permitted the hope that on their basis other compounds might be found which would specifically fit other groups of parasites. The high position of Ehrlich as a scientist and his masterly achievement would raise the estimate of therapeutics

to a higher level and also attract competent workers. The fundamental results obtained in animal experiments had been amply confirmed in the clinical observations upon relapsing fever and syphilis, though the clinical results were obscured by incompetent and biased writing. Salvarsan had various advantages over mercury in their respective actions on syphilis, but the proper fields of action of the two would be settled by unbiased and judicial methods of observation. In human syphilis a single injection of salvarsan was in many instances insufficient to sterilize the body permanently. On the other hand, it was found that repeated injections do not lead to the creation of resistant strains of spirochetes. Single large doses, therefore, were not a requirement, and the speaker suggested the employment of a series of repeated administrations of small doses, injected into the lumbar muscles. By this method, which could be easily used by the general practitioner, certain unpleasant by-effects would be obviated.

### THE INDICATIONS FOR SALVARSAN.

By Dr. S. Pollitzer, Manhattan. The time had not yet come, he said, for a final estimate of the value of this remedy, but we had already acquired sufficient knowledge of it to say that a great addition had been made to our resources against one of the most serious ills of humanity. There was naturally a certain amount of disappointment since we had found that the hope of a *sterilisatio magna* with a single dose was vain. Nevertheless, a single dose of salvarsan had a very great value in the treatment of syphilis. The most important indication for the exhibition of the drug was in all cases with fresh or infective lesions, chancres, mucous patches, condylomata, etc., as these were rendered harmless within a few days at most by one injection. A dose of salvarsan should be given in cases of extensive ulcerative lesion; in cases in which important organs were threatened; in cases in which lesions in the throat or the bones gave great pain; in infants with hereditary syphilis; in an early stage of tabes; in syphilis complicated by pulmonary tuberculosis, in which mercury and iodides were often harmful; in syphilitic cachexia, in which the wonderful tonic effect of the drug was especially valuable; and, finally, in cases in which the Wassermann reaction remained positive despite prolonged and thorough treatment with mercury. The indications for the re-injection of salvarsan were not yet clear, and that subject involved the whole question of the ultimate value of the remedy in the treatment of syphilis, as distinguished from the treatment of its symptoms. The speaker was employing salvarsan alone, that is, without mercury, in a selected number of cases, and his results seemed promising. He would, however, urge the medical public not to depend on salvarsan in the present state of our knowledge, and to help disabuse the general public of the idea that a dose of "606" is a cure for the disease. Every case of syphilis should receive a dose of the drug if this were really indicated, but, in addition, should receive the most active mercurial treatment.

### TECHNIC AND METHODS OF ADMINISTRATION OF SALVARSAN.

By Dr. Homer F. Swift, Manhattan. Salvarsan, he said, was a dihydrochloride of dioxydiamidoarsenobenzol, which is soluble as an acid and an alkaline salt, but not as a neutral one. It was made both neutral and alkaline by adding sufficient quantity of sodium hydrate. The alkaline solution for intramuscular injection was used first and was the most painful. The neutral suspension, prepared after the formula of Michaelis or Wechselmann, was used quite extensively because it was found the least painful. Acid salt, viz., salvarsan dissolved directly in water, has been used by a few workers, who claim it is the least painful. Lately, the suspension of dihydrochloride in oil has been used most extensively and seems to have given quite satisfactory results. Its chief advantage is its ease in preparation and the fact that a large dose of the salvarsan may be given in a small volume. In the intravenous injection only an alkaline solution should be used. It should be absolutely clear and so diluted that each 50 ccm. of the solution represents 0.1 gm. of salvarsan. It has been found that water is a more satisfactory diluent than normal sodium chloride. The acid solution should not be used intravenously, because of the danger of acidosis, and also because the mixing of acid salt with blood serum produces a heavy precipitate. In making intravenous injections, the injection of the salvarsan should be preceded and followed by sodium chloride, so as to be sure that no salvarsan escapes into the perivascular tissues. In making intramuscular injections, the needle should always be inserted empty, and all salvarsan should be washed out of it after the injection has been made. The intravenous method is the most efficient, but with it the drug is eliminated the most rapidly. It is also the least painful for the patient. The chief advantage of the intramuscular injection is its prolonged effect; the pain and necrosis are the chief objections to its use. A combination of intravenous and intramuscular method has been used to obtain both the rapid and prolonged effect. The use of small frequent intravenous injections is suggested. In this way, all the drug is utilized without the disadvantages of intramuscular treatment. The most efficient method has not been absolutely determined, but we are justified in proceeding with various combinations, for in any event we can promise the patient considerable benefit from the use of salvarsan.

### AN ANALYSIS OF THE CLINICAL AND SEROLOGICAL RESULTS OBTAINED IN THE TREATMENT OF ONE HUNDRED AND SEVENTY-FIVE CASES OF SYPHILIS WITH SALVARSAN.

By Dr. J. A. Fordyce, Manhattan. His report was a very favorable one. In view of the possibility of recurrences and of the difficulty of influencing the Wassermann reaction with a single dose, he advised a repetition in from one to four weeks, in addition to an active mercurial course. He had found salvarsan of special service in cases of malignant syphilis, where the results from it were more rapid and brilliant than he had ever observed from any other treatment. Failures were met with in advanced tabetics and paretics, and in five cases of hereditary disease, though in three of the latter the dose given was inadequate. He had had no accidents, although he had given nearly a hundred intravenous injections, and he did not believe salvarsan more dangerous than many other therapeutically active drugs. It was, however, necessary to observe the contra-indications to its use, while the greatest care should be exercised in the preparation of the solution and the technic of its administration. In only one case had he noted by-effects which gave him any anxiety.

### A FEW PLAIN TRUTHS ABOUT SALVARSAN.

In this paper Dr. W. S. Gottheil took a much less sanguine view than the preceding speaker. While salvarsan, as an additional weapon in our armamentarium, was valuable in certain cases, he said, it did not accomplish the marvels attributed to it. It was powerful in combating symptoms, but it did not cure, any more than mercury did. Indeed, evidences of the

persistence of syphilis appeared more frequently after its use than after treatment with mercury. Cases recently infected were the only ones by which its efficacy was to be estimated. Its disadvantages and dangers, with the large series of deaths reported, warned us that this remedy was not one for the profession at large. Mercury was still the antisyphilitic for general use. In early syphilis salvarsan had proved efficacious; here the remedial effects were equal to those of mercury, though it sometimes failed. In late cases it was as useless as mercury. The latest advice from high places was to give salvarsan first and then to recur to mercury. Cases of idiosyncrasy against mercury were not as frequent, however, as some would have us believe since the discovery of salvarsan. It might be stated, in general, that the latter was valuable in certain rare cases in the early stages where immediate action was called for, but was not indicated in ordinary cases.

THE BY-EFFECTS OF SALVARSAN.

DR. JAMES WINFIELD, Brooklyn, described the by-effects as local, organic and general. Among the effects mentioned were pain, infiltration, sloughing, necrosis (especially after subcutaneous injection), enlargement of neighboring lymphatic glands, a scarlatiniform eruption, urticaria, icterus, herpes zoster, pulmonary embolism and pneumonia, cardiac and vascular disturbances, hemorrhagic nephritis and acute necrosis of the renal convoluted tubules. Eye and ear troubles had also been noted, though these were often transitory and affections of the cerebrospinal system appeared to increase after the use of the remedy. No serious effects were produced on the gastro-intestinal tract. The vital organs, he said, should be carefully examined before the drug was resorted to.

Another paper read in the symposium was "The Action of Salvarsan on the Wassermann Reaction," by DR. HOWARD FOX, and in the discussion DR. GEORGE H. FOX spoke of the use of salvarsan in leprosy and psoriasis, citing cases in which it appeared to be of service.

THE RELATIONSHIP OF TABES TO GENERAL PARESIS; ARE THEY THE SAME DISEASE, DIFFERING ONLY IN THE SITUATION OF THE LESION?

By DR. E. D. FISHER, Manhattan. Having pointed out the anatomical lesions in these two diseases, both of which were parasyphilitic or metasyphilitic affections, he said that in one hundred cases of general paresis of cerebral and tabetic type but one presented anything resembling a classical case of tabes. In the two classes of cases he had observed, both in public and private practice, those which approached each other in minor characteristics differed essentially in the more marked symptoms. It was impossible to believe that a disease essentially spinal in its symptoms and pathology, and usually lasting at least twenty years, could be the same (differing only in the seat of its lesion) as a disease commonly limited to three years and whose pathology was essentially cerebral.

THE NERVOUS WOMAN.

By DR. E. B. ANGEL, Rochester. His contention, based on the records of over a thousand private cases, was that nervousness, which he distinguished from neurasthenia (the latter being a true exhaustion neurosis), depends very largely upon a toxemia resulting from disturbances in metabolism. Hence, worry was a symptom, not a cause, of the disorder; nor as causal influences were pelvic disorders as intimately associated with nervousness as generally supposed. The excessive use of proteid food, with intestinal indigestion and inefficient oxidation and elimination of waste products, had caused the trouble in from 70 to 80% of his patients, most of whom had indoor occupations. In two thirds of them there was abdominal distention from fermentation. In the routine examination of the urine, which was apt to be highly acid, he noticed, in a large proportion of instances, that a marked pigment line, dark brown or red, developed at the point of contact with the underlying nitric acid. Before commencing a course of treatment a thorough physical examination of the patient was important, in order to exclude any organic disease which might give rise to the symptoms present.

TAKING THE CURE AT CARLSBAD.

By DR. H. G. WATSON, Manhattan. He gave a lively description of Carlsbad, the life there, and "taking the cure," which consisted of four principal things: Drinking the waters, taking the proper baths, dieting and resting. He also mentioned some of the contra-indications to the Carlsbad treatment.

PARALYSIS OF THE UPPER EXTREMITY DUE TO NERVE INJURY.

By DR. N. JACOBSON, Syracuse. The paper was based upon five cases. The first three concerned injury of the musculospiral nerve, with the characteristic wrist-drop, limited extensor movements of the fingers, and limitation of sensation. Two of them occurred as complications of fracture of the humerus, and the other case was one of nerve injury following a lacerated wound in the lower third and radial side of the arm. In the fourth case a fracture through the neck of the scapula led to displacement inward of the head of this bone, with pressure upon the brachial plexus; and the fifth dealt with a complete division of the fifth cervical nerve from a penetrating wound in the neck. In each instance the resulting paralysis was improved or entirely cured by surgical operation.

THE CLINICAL OBSERVATION OF CARDIAC ARRHYTHMIAS FROM THE MODERN STANDPOINT.

By DR. W. B. JAMES, Manhattan. He described two classes of arrhythmias; one, called rhythmical irregularities, in which there was a fixed interval between the irregularity and the extra-systole to which it belonged, and one in which the irregularity followed no rule whatever. This absolutely irregular pulse, which was due to fibrillation of the auricle, had formerly been considered to offer the worst possible prognosis, but this was not the case. If there was a good ventricle, digitalis could be relied upon to control the auricular fibrillation. On the other hand, the rhythmically irregular pulse was not so amenable to treatment. The paper was illustrated by electrocardiograms taken at the Presbyterian Hospital with the Einthoven string galvanometer, and Dr. James described the apparatus and the method of taking records with it.

*Wednesday, April 19.*

ARTERIOSCLEROSIS, OR THE CARDIOVASCULAR DISEASE.

By DR. L. F. BISHOP, Manhattan. He said he would propose the term "the cardiovascular disease" for that clinical syndrome in which with disease of the heart and blood-vessels there was correlated auto-intoxication, neurasthenia, renal degeneration, etc. Arteriosclerosis he considered an unsatisfactory name because it had become associated with a particular pathological condition of the vessels and thus tended to

divert the attention from the general distribution of the disease. There was a toxic degeneration of the circulatory organs of slow development, often inducing at first lowered blood-pressure and symptoms of neurasthenia, and followed by albuminuria and variable blood-pressure, with a diffused soft systolic murmur heard to the left of the sternum. Later there resulted high blood-pressure, protein intolerance, and definite structural changes in the heart and arteries, and the disease terminated in the typical picture of Bright's disease, with contracted kidney, dilatation of the heart, anasarca and almost complete protein intolerance. The great underlying cause of this whole process he believed to be intestinal putrefaction. At least, in his experience, covering the observation of more than forty thousand specimens of urine, intense indicanuria had always been present except in some advanced cases in which the original cause was not active and the suffering present was due to the acquired structural changes. Much might be accomplished by treatment if the case were not seen too late, and the general plan advocated by the speaker consisted of dietetic, hydriatic and psychotherapeutic management according to Nauheim methods.

### THE SIGNIFICANCE AND THERAPY OF HIGH BLOOD-PRESSURE.

By Dr. J. F. Rooney, Albany. He described three main types of high-pressure cases, — general, splanchnic and nephritic, — with the characteristics of each and the indications for treatment. In speaking of the therapeutics he gave the results of his experience with vasodilators, his conclusions being as follows: (1) The utility of the vasodilators is apparent conversely with the acuteness of the pathological condition. (2) Eliminative measures, hot air, carbon dioxide baths, and catharsis are of much more marked effect in the toxic group of cases. (3) Venesection, which has fallen into undeserved disuse, is of great service in acute toxic cases accompanied by dilatation of the heart. (4) Blood-pressure determinations alone cannot differentiate between tabetic crises and intra-abdominal perforations. (5) The effect of nitroglycerin is as prolonged as any of the nitrite group except erythrol nitrate, and its rapidity of action nearly as great as that of amyl nitrite. (6) The employment of the aconite group as vasodilators is pharmacologically unsound and, except in the toxemia of pregnancy with a strong heart muscle, should be entirely discontinued.

### THE HYDROTHERAPEUTIC TREATMENT OF CHRONIC DISEASE OF THE HEART.

By Dr. J. M. Swan. He especially advocated the Nauheim method, and expressed the opinion that the increased activity of the skin produced by this treatment, with the effect of lessening the resistance of the peripheral vessels, had much to do with the results noted.

### OLIVE OIL IN POST-OPERATIVE VOMITING NAUSEA.

By Dr. C. B. Hyde, Brooklyn. He recommended the administration of two ounces of pure olive oil after all operations, just at the moment the patient begins to recover consciousness. It almost always produced a single explosive attack of vomiting, after which the stomach remained at rest. The effect was equally good, however, if the oil was not vomited.

### CEREBRAL COMPRESSION.

By Dr. E. R. McGuire, Buffalo. He gave an outline of the etiology, diagnosis, localization and surgical treatment of the condition, and cited illustrative cases.

### DEVELOPMENTAL DEFECTS OF THE ABDOMINAL VISCERA AND THEIR SURGICAL SIGNIFICANCE.

By Dr. W. F. Campbell, Brooklyn. As the result of observations in five hundred autopsies, as well as of clinical investigation, it was his conviction that many of the abnormal conditions of the abdominal viscera hitherto regarded as acquired were in reality attributable to developmental defects. In the course of evolution the mesenteries had become shortened, and whereas in the quadruped the abdominal wall acted as a hammock, in the biped it performed the function of a corset. Such conditions as enteroptosis, nephroptosis and Lane's kink, he believed, were the result of developmental defects, and not of wearing corsets. In the treatment of enteroptosis, while mechanical supports had their place, much more attention should be paid to gymnastic exercises than was usually the case. Lane's kink was instrumental in the production of intestinal stasis, simulating chronic appendicitis, and should be treated by operation.

### DEDUCTIONS FROM CLINICAL EXPERIENCE IN THE USE OF A POLYVALENT BACTERIAL VACCINE.

By Dr. J. M. Van Cott, Brooklyn. He had treated 75 cases of infection by this method, of which 35 were erysipelas, 18 puerperal sepsis, and the remainder miscellaneous infections. All the patients were in bad condition at the time the treatment was commenced, and most of them did very well under it. There were, however, two deaths each among the erysipelas and the puerperal cases. Such vaccination was useless where the patient's system was overwhelmed by toxins. He employed intramuscular injections of ½ ccm., or 375 million dead bacteria, and repeated the injections at four days' intervals. More or less muscular discomfort was caused, but no constitutional depression. Stock vaccines, he thought, were preferable to the autogenous, as they were more quickly and readily obtained. His object in presenting this paper, the speaker said, was to bring up the question whether it was advisable for the general practitioner who is not prepared to take the opsonic index or make blood examinations to make use of these vaccines.

### THE SURGICAL TREATMENT OF EXOPHTHALMIC GOITRE.

By Dr. Martin Tinker, Ithaca. No sensible man, he said, would consider it logical to treat tobacco heart or amblyopia and at the same time allow his patient to continue the free use of tobacco. It was just as illogical to treat exophthalmic goitre with drugs without removing the source of the excessive thyroid secretion. Granted that surgical interference was called for, it was certainly of great importance that this should be resorted to before irreparable damage had been done to any of the vital organs. He had done one hundred and fifty-one consecutive operations without fatality. These were not picked cases, and many of the patients were in very bad condition. He had refused to operate in only three instances. In these the cases were hopeless, one dying in twenty-four hours and the other two within three weeks from the time they were seen.

### MUTUAL HELPFULNESS IN THE CONSERVATION OF PUBLIC HEALTH.

In this paper Dr. W. A. Howe, of Phelps, deputy commissioner of the State Department of Health, made a plea for more complete co-operation between the medical profession and the Department. The supplies of the latter, such as vaccine virus, diphtheria and tetanus antitoxins, etc., were always at the dis-

posal of physicians, and the Department was at all times glad to furnish assistance in the way of laboratory investigation, an expert diagnostician or a sanitary engineer.

### MALIGNANT TUMORS OF THE KIDNEY.

By DR. HENRY ADSIT, Buffalo. He said these growths might be divided into five classes: (1) Hypernephroma, by far the most frequent. (2) Carcinoma, extremely uncommon. (3) Mixed tumors occurring in children, not infrequent. (4) Sarcoma, also a disease of childhood, and practically a subdivision of the last group. (5) The very rare condition of papilloma of the pelvis of the kidney. Although hypernephromata occurred in over 90% of all cases, they were the most difficult to diagnose. Their pathology was puzzling, but the weight of evidence was to the effect that they are of epithelial origin and a malignant development of aberrent adrenal tissue. Many cases reported as carcinoma had been found to be hypernephroma. Dr. Adsit had operated in six cases, five of which recovered.

### THE DIAGNOSIS AND OPERATIVE TREATMENT OF RENAL CALCULUS.

By DR. P. M. PILCHER, Brooklyn. In making a diagnosis he warned against the dangers of manipulative procedures. It was necessary to rely chiefly upon the x-ray for determining the location, size and number of calculi, and the extent of renal destruction, when such was present. The paper included a description of the different varieties of stone and the most satisfactory operation for each.

### AUSCULTATION OF THE COUGH.

By DR. A. H. GARVIN, Raybrook. This, he said, was a valuable aid to diagnosis and should be practiced at four different periods of the cycle of respiration. It was of special importance during inspiration as a means of information in advanced stages of tuberculosis.

### EXOPHTHALMOS A COMMON SYMPTOM OF BRIGHT'S DISEASE.

By DR. H. C. GORDINIER, Troy. Curiously enough, he said, this was entirely overlooked in the textbooks, and it was only of late that attention had been called to it in current medical literature. Yet it was a fact that exophthalmos, of varying degree, occurred in nearly one half the cases of chronic nephritis, usually associated with hypertension and without thyroid hypertrophy or marked tachycardia.

### THE PRE-CANCEROUS STAGE.

By DR. PARKER SYMS, Manhattan. The fact was now generally recognized that certain conditions and lesions predispose to cancer. Benign tumors were pre-cancerous factors, and scars, chronic inflammation and ulceration, or almost any cause of prolonged irritation, might prove sources of malignant disease. The importance of thus recognizing such factors as these in the etiology of cancer could not be overestimated, and the early and complete removal of cancer precursors constituted the prevention of cancer in the pre-cancerous stage. The speaker especially urged the extirpation of all mammary tumors as soon as discovered.

### CANCER IMMUNITY IN ITS PRESENT STATUS.

By DR. H. R. GAYLORD, Buffalo. He reviewed the evidence in favor of passive and of active immunity, and said that a certain immunity seemed to be conferred by inoculating an animal with a growth from a different species. It had been found that this immunity was not directed against the cancer cell, but against growth, being entirely independent of the former. The question of vaccination had again arisen, and at the late convention in Paris six cases were reported as cured by this method. In all probability, however, the field for the employment of vaccination would be quite limited, though early cases might be amenable to it.

### INTESTINAL TUBERCULOSIS AND ITS TREATMENT.

By DR. S. G. GANT, Manhattan. Having discussed the relative frequency of primary and secondary tuberculosis of the intestine, he classified the disease into the enteric, entero-peritoneal, stenotic and glandular varieties; after which he referred briefly to the symptoms and diagnostic points of each. Then, after mentioning the most reliable methods for the non-surgical treatment of intestinal tuberculosis, he spoke of the relative usefulness and described the most important points of the technic of colostomy, cecostomy and appendicostomy, and most reliable operations for the relief and cure of this condition; in conclusion, giving the results to be expected from them. He called especial attention to the value of cecostomy, which, when combined with the enterocolonic irrigator, provided a certain means of flushing both the large and small intestine, either separately or together.

### CHRONIC APPENDICITIS: A CRITICAL STUDY OF POST-OPERATIVE END RESULTS.

By DR. E. MACD. STANTON, Schenectady. In studying the post-operative condition of patients operated under the clinical diagnosis of chronic appendicitis, it was found that 96% of the cured cases had, before operation, suffered from attacks of indigestion characterized by symptoms analogous to the earliest symptoms of acute appendicitis. Pain confined chiefly to the right lower quadrant of the abdomen, and not associated with attacks of epigastric pain, was seldom due to the appendix, and, before making a diagnosis of chronic appendicitis, every other possible condition should be excluded. The majority of errors in diagnosis were made in cases characterized by right inguinal pain associated with chronic constipation, where there was an unusually long or dilated cecum with enteroptosis. The paper included an analysis of one hundred cases which had been operated under the clinical diagnosis of chronic appendicitis.

Other papers presented at the meeting were, "Vaccination in the Army," by Col. John Van Hoff, Medical Corps, U. S. A.; "Radiographic Diagnosis of Lesions of the Gastro-Intestinal Tract and Cinematographic Demonstration of the Peristalsis in Normal and Pathological Cases," by Dr. L. G. Cole, Manhattan; "The Prevention of Insanity," by Dr. A. W. Ferris, president of the State Commission in Lunacy; "The Prevention of Gonorrheal Ophthalmia," by Dr. Lucien Howe, Buffalo; "Report of a Case of Gunshot Wound of the Abdomen with Fifteen Intestinal Perforations," by Dr. E. A. Vander Veer, Albany; "A New Method of End-to-End Anastomosis," by Dr. A. L. Soresi, Manhattan.

The following officers were elected for the ensuing year: President, Dr. W. C. Phillips, Manhattan; First Vice-President, Dr. P. W. Van Peyma, Buffalo; Second Vice-President, Dr. W. F. Campbell, Brooklyn; Third Vice-President, Dr. P. R. Hervey, Oswego; Secretary, Dr. W. R. Townsend, Manhattan; Treasurer, Dr. A. Lambert, Manhattan.

## Book Reviews.

*A Manual of Diseases of the Nose, Throat and Ear.* By E. Baldwin Gleason, M.D., Clinical Professor of Otology at the Medico-Chirurgical College, Philadelphia. Second revised edition. Philadelphia and London: W. B. Saunders Company. 1910.

The first edition of this book was reviewed in the Journal of Nov. 21, 1907. This edition has been largely rewritten, and slightly enlarged. The nose and throat occupy about 300 pages, the ear 200, and formulæ and index about 60 more. It is a condensed textbook, in many ways convenient and attractive, generally conservative, but not particularly well balanced. Some important subjects receive scant attention, others do not include the more commonly accepted etiology and treatment. The type is new and the appearance of the book excellent.

*The Cancer Problem. A Statistical Study.* By C. E. Green, F.R.S.E. Edinburgh: William Green & Sons. 1911.

Though prevented from becoming a physician, as he tells us in his Latin apology, Mr. Green has retained from his days as a medical student an interest in the cancer problem, which he has attacked not from the experimental but from the statistical point of view by the deductive method of Sherlock Holmes. From the analogy of plant tumors, he argues that animal cancers are probably due to a fungoid parasite which so stimulates the cells of the host that they become themselves parasitic. This unknown organism should, therefore, be closely akin to the *Plasmodiophora brassicæ* which causes plant cancer. The growth of *Plasmodiophora brassicæ* is especially favored by sulphurous substances, and inhibited by calcium and copper. The human occupations most prone to cancer — chimneysweeps, brewers and furriers — are those most exposed to sulphur derivatives; those most immune — tanners, copperworkers and paper-makers — are those who come most in contact with lime or copper. Moreover, the regions and houses where cancer is commonest are those where coal is burned and where chimneys draw poorly, that is, where $SO_2$ is present in the air. Mr. Green's book seems like an ingenious *tour de force;* but the argument is plausibly drawn, and there is just enough conceivable possibility that it may be right to make it worth reading.

*The Care and Training of Children.* By Le Grand Kerr, M.D. New York and London: Funk & Wagnalls Company. 1910.

This little book, written for "the average busy parent," consists of brief, sensible chapters on clothing, diet, bathing, sleep, education, punishment and other essential elements of life in which children need watchful, intelligent and sympathic guidance and help. Particularly pertinent is the discussion of the physician's duty towards children whose parents are unable or unwilling to give them proper training and care.

*The Physiology of Reproduction.* By Francis H. A. Marshall, M.A. (Cantab.), D.Sc. (Edin.), with a preface by Prof. E. A. Schäfer, Sc.D., LL.D.,F.R.S., and contributions by William Cramer, Ph.D., D.Sc., and James Lochhead, M.A., M.D., B.Sc., F.R.C.S.E. With illustrations. London, New York, Bombay and Calcutta: Longmans, Green & Co. 1910.

This volume is a scholarly and very complete treatise on the physiology of the sexual functions in man and other animals, and possesses, besides, considerable literary merit both in style and in the felicity of the quotations introductory to each chapter. The section on the biochemistry of the sexual organs is written by Dr. Cramer, and the chapters on fetal nutrition and the metabolism of pregnancy by Dr. Lochhead. The illustrations are many and excellent. Though addressed primarily to biologists, the book should be of interest and value also to physicians and to that new and growing class of philosophers and publicists who are concerned with the science and art of eugenics.

*Radium.* Its Physics and Therapeutics. By Dawson Turner, B.A., M.D., F.R.C.P. Edin., M.R.C.P. Lond., F.R.S. Edin. New York: William Wood & Co. 1911.

This book aims to present in compact form the known facts about the physical phenomena of radio-activity, and the methods, indications and value of its use in the treatment of disease. It is well written and illustrated and should prove a serviceable manual of this new and important subject in medicine.

*Internal Secretions from a Physiological and Therapeutical Standpoint.* By Isaac Ott, A. M., M.D. Easton, Pa.: E. D. Vogel. 1910.

This small volume presents three lectures delivered by the author before students of the Medico-Chirurgical College, Philadelphia, on the internal secretions of the parathyroids and of the hypophysis, and on the correlation of glands with an internal secretion. It is a timely and useful contribution to the study of a subject which is attracting considerable present medical interest.

*The Proceedings of the Charaka Club.* Volume III. New York: William Wood & Co. 1910.

This beautifully printed limited edition of the proceedings of this interesting organization presents a number of illustrated essays by its distinguished members on topics whose variety of nature and treatment shows that breadth of interest and literary ability are not incompatible with professional eminence in medicine. "*Dulce est dissipere in loco,*" and in selecting the groves of Academe for their "dalliance with the Muses," these "Children of the Sage" have given pleasure not only to themselves but to those who are fortunate enough to be their privileged readers.

Such a volume goes far to remove the reproach of professional engrossment, often visited upon physicians as a class, and to prove, if one may adapt a quotation from Shakespeare, that "men may be doctors and yet human, too."

*Gynécologie Opératoire.* Par HENRI HARTMANN, Professeur de Médecine opératoire à la Faculté de Médecine. Avec 422 figures dans le texte dont 80 en couleur. Paris: G. Steinheil, editeur. 1911.

This is a book of 498 pages. Although the text is devoted largely to the subject of operative gynecology, as the title indicates, Part I, pages 1–87, is given up to the examination and chapters on minor gynecology, electrotherapy, symptoms, hydrotherapy and massage, and here and there throughout the work are chapters on local treatment, replacement of the uterus, etc. Foreign authors are quoted freely, and their operations described.

In the portion on plastic operations on the cervix and the walls of the vagina, the usual excellent practice in this book of placing the rarer operations in a supplementary chapter at the end has been forsaken, and many obsolete operations, such as the Freund operation for prolapse, have been scattered through the text. Altogether this is one of the most unsatisfactory portions of a good book.

The colpotomies, the removal of fibroids by the vagina, vaginal hysterectomy, as well as hysterectomy by the paravaginal route, and Oui's operation for inversion, are described satisfactorily and fully. The Alexander operation, on the other hand, is inadequately described, and the figures are poor, and the same is true of abdominal hysterectomies for chronic metritis and fibroids. Hysterectomy for cancer and the operations on the tubes, ovaries and uterine ligaments are well treated.

An attempt has been made to cover the ground of the effect on subsequent pregnancy of operations on the cervix and on the uterus for fibroma. The book closes with chapters on the disorders of menstruation, sterility, the surgery of the urinary organs, and the treatment of fistulæ, all handled briefly but well.

*Common Practical Therapeutics.* By ALBERT ROBIN, Professor of Clinical Therapeutics in the Faculty of Medicine at Paris; Member of the Academy of Medicine. Paris: Vigot Frères. 1910.

This volume by Dr. Robin, written with charming and customary Gallic lucidity of style, presents the author's lectures on therapeutics at the Beaujon Hospital. Under the general headings of diseases of the stomach, intestines, liver, kidneys, vessels, and nerve-system, he considers the principles and details of treatment of a large number of the common ailments of mankind, serious and trivial. Not all his methods are in accord with American therapeutic custom, but as a manual of French practice his volume should be of value to students and to physicians.

THE BOSTON
# Medical and Surgical Journal.

THURSDAY, MAY 18, 1911

*A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.*

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

*All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 800 Paddock Building, 101 Tremont Street, Boston.*

## THE PASSING OF A MEDICAL LANDMARK.

THE old building of the Harvard Medical School on North Grove Street, now the property of the Massachusetts General Hospital, is being torn down to make way for a new structure. The passing of this familiar medical landmark in Boston removes one more of the visible ties that unite us with a distinguished past. This building was erected in 1846 on a site of land given for the purpose on Feb. 28 of that year by George Parkman.

Since its removal to Boston from Cambridge early in the nineteenth century, the Harvard Medical School had been established on Mason Street. Here, despite conflicts with the Berkshire Medical Institution and sundry private medical schools, it had thriven, so that, in 1845, its records state with satisfaction that "the faculty are willing to consider the increased number of pupils (one hundred and fifty-seven) in this institution, which has doubled within the last five years, as an evidence that the advantages which they offer to the candidates for medical degrees are becoming appreciated by the community, and it gives them pleasure to add that they believe a greater number of teachers for the different medical schools in the United States in proportion have been taken from their graduates than from any other medical institution in this country. They think that they have a right to regard this as some evidence of the success of their endeavor to give a thorough course of medical instruction." As the course then required for a degree in medicine was three years, the classes in 1845 were of approximately the same size as at present.

Owing to this rapid increase in numbers, the building on Mason Street became cramped and inadequate. Accordingly, on April 11, 1846, the

Harvard Corporation voted "to sell the Mason Street estate and use the funds for the erection of a new building for the Medical School on the land presented by Parkman." At this time the only structure nearby was the Bulfinch Building of the Massachusetts General Hospital, by whose westerly end flowed the Charles River; and it was wisely intended that school and hospital should develop in the normal contiguity which befits their close association. To provide for the construction of the new school the Corporation further voted: "That in case the proceeds of the sale of the estate in Mason Street shall not be sufficient to complete the new building on Grove Street according to the plans adopted, the treasurer be, and he is hereby authorized, to spend a further sum not exceeding five thousand dollars for the purpose, provided that the professors of the Medical School shall by a suitable instrument in writing signed by them pledge to the college such portion of the fees received by them from the medical students as shall be sufficient to pay the interest on said sum advanced by the treasurer . . . at the rate of six per centum per annum payable semi-annually until the said sum shall be reimbursed to the college treasury." One cannot help wondering what would happen now if members of a medical faculty were asked to help pay for a new school building out of their salaries.

Like most new buildings, the North Grove Street school cost more than had been anticipated, and in 1847 the treasurer was authorized to expend for its completion a further sum not exceeding nine thousand dollars, and the professors bound in surety to pay, not only the interest as before, but the principal as well. The building was finished and occupied in the same year, and continued to be used until the removal of the school in 1883 to the building on the corner of Boylston and Exeter streets.

The year in which the school became established on North Grove Street was one of moment in its history. On Feb. 15, 1847, Dr. J. C. Warren resigned his position as Hersey Professor of Anatomy and Surgery. On April 3, 1847, the title of this chair was changed to that of Hersey Professor of Anatomy, and Jeffries Wyman was elected to fill it. The Corporation further created two new professorships, with the titles Professor of Pathological Anatomy and Parkman Professor of Anatomy and Physiology, and appointed to them respectively John Barnard Swett Jackson and Oliver Wendell Holmes. In September, 1847, Walter Channing resigned as Dean of the school, and on Oct. 2 Holmes was appointed in his place. At the opening of the school in the new North Grove Street building, therefore, began the professorial and administrative career of some of its most distinguished teachers.

The early history of the school at North Grove Street was also associated with numerous episodes of interest and importance in connection with local tradition and the development of medical education, many of which are described at length in Harrington and Mumford's "History of the Harvard Medical School," from which the above quotations have been taken. The demonstration of surgical anesthesia by ether took place while the new building was in process of erection, and gave an immense impulse to popular and professional interest in the possibilities of medical science. The Harvard School began the work of medical education in its new quarters with a brightness of prospects which not even the sinister events of the Parkman murder in 1849 could long obscure. For thirty-seven years this building served the needs of medical education in Boston. It was the school of the fathers of the present medical generation, of the men who created the temper and ideals of our profession in Boston. When the Medical School was removed to Boylston Street, the Grove Street building was used for twenty-five years by the Harvard Dental School. On the removal of the latter to its new building on Longwood Avenue, in 1908, the Grove Street building was acquired by the Massachusetts General Hospital and has stood vacant since that time.

The demolition of this historic building marks the close of an epoch in the history of medical education. Opened at the beginning of a new era in medicine, it has been associated with many distinguished names and some notable events. Its story will soon be only a memory, but the work done within its walls has passed permanently into the fabric of the profession and has led to results and achievements that can never perish.

## NATURE AND EUGENICS.

THE wail of the eugenist is at present loud in the land. Everywhere he sees the fit perish by race suicide and the unfit increase and multiply exceedingly and survive to inherit the earth: and great are his grief and despondency thereat. Doubtless it is true that one may observe many highly specialized and efficient individuals upon whose evolution the labor, conscious and unconscious, of preceding generations had been expended, failing to reproduce themselves and secure

the benefits of their valuable germ-plasm to succeeding ages. This may seem, and no doubt often is, very wasteful and unfortunate. But then many natural processes are wasteful, and the question rises whether the loss is really so great as it appears, since somehow it seems generally to be made good from below. Irresistible aspiration is one of the beneficient provisions by which nature keeps her stock of germ-plasm from permanent deterioration.

Now it is a fairly well-established fact that any living strain bred exclusively from its own like tends after a certain time to retrograde. Barring a few exceptional instances, it seems impossible for a high grade of evolution to be maintained long in a pure stock without retrogression or extinction. Retrogression in such cases is the provision by which such stock is mercifully enabled to preserve itself by merging again with the common welter of existence. If extinction be the choice, it may be tragic, but it may also be for the best. At any rate, it is probably not always the dire calamity which it is considered by the eugenist. For out of the undifferentiated sea of humanity is always raised up new material to take the place of that which has been lost, to assume the duties of evolution and to discharge them with the rejuvenated vigor and zest of new experience.

The possible fallacy in eugenics lies in regarding the loss of a good type as an unmixed evil. There is no proof that it is necessarily so. Nothing in human evolution is stable. It is dependent for its very nature and existence on the perpetual flux and flow of incessant kaleidoscopic recombination. The highly specialized, carefully elaborated form perishes, but before dying it has done its work, and that is enough. One may lament the loss of the type, of the finished experiment, but nature "looks and laughs at a' that." She cares nothing for the individual who tops above his fellows, she cares only for the slow improvement of the undifferentiated type. With her all is experiment, and from the alchemic crucible of her laboratory she can produce new types, different perhaps from those which have passed away, but better adapted to their changing environment. The process is as perennial and immortal as life and romance:

> "In dock and deep, and mine and mill,
> The Boy-god reckless labors still."

Let us then take heart in spite of the eugenist's lamentations. For we may courageously refer him to the superb examples which time has afforded of the replacement of lost types with better; and, by way of refutation, may bid him

> "Fear not lest existence, closing your
> Account and mine, should know the like no more;
> The eternal Saki from that bowl has poured
> Millions of bubbles like us, and will pour."

Time may and will efface the "cunning'st pattern of excelling nature," but she will excel herself again, and out of the common earth will fashion a new type, nobler and fitter than its predecessor.

## THE ANNUAL MEETING OF THE MASSACHUSETTS MEDICAL SOCIETY.

THE Massachusetts Medical Society has just published the program of the annual meeting to be held on Tuesday and Wednesday, June 13 and 14. The meetings will be held in the buildings of the Harvard Medical School, except the Shattuck Lecture, which will be in John Ware Hall, at the Boston Medical Library, as in former years; the dinner, which will be in Symphony Hall, and an afternoon tea and demonstrations at the Tufts College Medical School, on Huntington Avenue. There will be many demonstrations and exhibits in the different laboratories of the Harvard Medical School during both days of the meeting and special efforts have been made to have full and attractive programs of the meetings of the Sections. Tuesday morning the Section of Medicine will give a symposium on Salvarsan from the clinical standpoint, seven papers and demonstrations. At the same time the Section of Surgery will give a symposium on Anesthesia, four papers and demonstration of apparatus, and two papers on fractures. In the afternoon of Tuesday the Section of Medicine will hold a symposium on circulatory disorders, four papers, and the Section of Surgery a symposium on surgical diseases of the kidney, four papers, and papers on surgical treatment of pyloric stenosis and malignant disease of the large intestine. The Section of Tuberculosis will hold a symposium on outdoor schools and open-air rooms for children on Tuesday afternoon beginning at 2 P.M.

The Shattuck Lecture Tuesday evening will be by Dr. R. C. Cabot.

At the annual meeting on Wednesday morning Dr. George W. Gay will read a paper on suits for alleged malpractice, and E. H. Bradford and W. J. Collins on the treatment of spinal curves and co-existent epidemic cerebrospinal meningitis and malaria respectively. Dr. M. H. Richardson will give the annual discourse.

The annual dinner will be given in Symphony Hall at one o'clock and following the dinner the annual ball games between nines from the different district societies will be held at one of the country clubs near Boston, the members being taken there in electric cars. The challenge cup is now held by the nine from the Middlesex South District Society, and it is understood that preparations are being made by the rival nines to wrest the cup from them.

## EXPEDITION TO STUDY MOUNTAIN SICKNESS.

It is announced that during the months of July and August in the coming summer, an expedition will be made to Pike's Peak, Colorado, for the purpose of making extensive studies of mountain sickness. The investigations are to be under the direction of Dr. Yandell Henderson, assistant professor of physiology at the Yale Medical School. With him will be associated two English physicians, Dr. J. S. Haldane, brother to the present British Secretary of State for War; and Dr. C. Gordon Douglas. Dr. Haldane is regarded as an authority on caisson disease. Dr. Douglas, who is a Fellow of St. John's College, Oxford, took part recently in similar international Anglo-German medical investigations at Teneriffe, in the Canary Islands. Dr. Edward C. Snyder, of Colorado Springs, Colo., will also assist in the work. It is hoped that results of definite value may be obtained by this experimental research in a disease whose nature is not as yet fully understood.

## WORK OF THE ARMY MEDICAL CORPS IN THE ERADICATION OF SMALLPOX.

In the issues of the JOURNAL for March 23 and May 4, we referred editorially to the eradication of smallpox from the Philippine Islands and from Cuba since the occupation of these territories by the United States in 1898. In commenting on the part performed in this work by the Public Health and Marine-Hospital Service, it was not our intention to withhold due credit also from the United States Army Medical Corps, under whose officers, indeed, systematic vaccination and quarantine were first begun in Cuba. In Porto Rico, too, successful efforts to eradicate smallpox were carried out, immediately after the American occupation, under the chief surgeon of the Army Medical Service in that island. This work of army medical officers in Porto Rico, and under Gen. Leonard Wood in Cuba, is described at length in the annual report of the Surgeon-General of the Army to the Secretary of War for the year ending June 30, 1899. The extermination of this endemic pestilence is one of the most beneficent results of the Spanish War, and the labor and enterprise of United States Army surgeons in its accomplishment should not be forgotten in recording so great and creditable an achievement.

## MEDICAL NOTES.

APPOINTMENT OF HARVARD EXCHANGE PROFESSOR. — Report from Breslau, Prussia, states that, on May 10, Dr. Willy Kukenthal, professor of zoölogy in the University of Breslau, was appointed exchange professor at Harvard University for the academic year 1911–12.

SCHOOLS FOR MOTHERS IN ENGLAND. — It is stated that there are now, in various British municipalities, eighty schools for mothers, in which the principles of hygiene and infant care are taught to women of all classes. The largest and most important of these are at Birmingham, Sheffield, Cardiff, Glasgow, Dundee and Bath.

SMALLPOX QUARANTINE AT KEY WEST. — Report from Key West, Fla., states that the schooner *Horatio G. Foss* is quarantined at that port with a case of smallpox aboard. This vessel, which is owned in Boston, sailed on April 29 from Mobile, Ala., for Porto Rico.

A LIVING ENGLISH CENTENARIAN. — On April 5, Mr. Augustus Gordon Hake, of Brighton, England, celebrated the supposed centennial anniversary of his birth. He is said to have been born in 1811, at Exeter, England. He was called to the bar in 1835, and is at present believed to be the oldest living barrister. He practiced his profession until recently and is said to be still in excellent health. He has been a resident of Brighton for the past sixty years.

AMERICAN THERAPEUTIC SOCIETY. — The twelfth annual convention of the American Therapeutic Society was held in Boston on May 11, 12 and 13 of last week. The sessions were at the buildings of the Harvard Medical School. The annual address was delivered by the outgoing president, Dr. Harvey W. Wiley, of Washington, D. C., on the subject of "Alcohol as a Medicine and as a Beverage." Dr. Alexander D. Blackader, of Montreal, P. Q., Canada, was elected president of the society for the ensuing year.

OHIO STATE MEDICAL ASSOCIATION. — The sixty-sixth annual meeting of the Ohio State Medical Association was held on May 9, 10 and 11 of last week at Cleveland, Ohio. At the general meeting on Wednesday, May 10, the annual address in medicine was delivered by Dr. Hobart Amory Hare, of Philadelphia, on "The Danger and the Duty of the Hour," and the annual address in surgery by Dr. J. Chalmers Da Costa, of Philadelphia, under the title "Behind the Office Door." At meetings of the various special sections, papers were read by the following physicians, now or formerly of Boston: Dr. Charles M. Green, Dr. Richard Dexter and Dr. G. Bourne Farnsworth. On Thursday, May 11, were held the graduating exercises of the Lakeside Hospital Training School for Nurses.

THE MEDICAL LIBRARY ASSOCIATION. — The fourteenth annual meeting of the Medical Library Association was held May 9 and 10, 1911, at the Marlborough-Blenheim Hotel, Atlantic City.

The first session was held Tuesday evening and the following program was carried out: President's address, Dr. J. H. Musser, Philadelphia, Pa. Papers: "Hospital Records in Relation to the Hospital Librarian," Mrs. Grace W. Myers, Boston, Mass.; "The Establishment of Medical Libraries in County Medical Societies," Dr. Carl Black, Jacksonville, Ill.; "The Changes in Medical Periodical Literature since January, 1909," Mr. C. Perry Fisher, Philadelphia, Pa.

The second session was held the morning of May 10. The meeting considered the reports of the various committees and the election of the officers.

A FALLACIOUS ARGUMENT FOR LIMITATION OF OFFSPRING. — On Thursday, May 11, was opened, at Chicago, a Child Welfare Exhibit, intended to illustrate the various progress that has been made in the science and art of improving the health and securing the hygienic development, education and training of children. The exposition will continue for a fortnight. In the health section of this exhibit, as an argument in favor of the limitation of families, is said to be posted a placard bearing the words: "The bigger the family, the higher the death-rate among the children." In support of this statement are adduced figures from investigations made by Dr. Alice Hamilton among sixteen hundred families in the slum districts of Chicago, indicating that "in families of four children the death-rate is 118 per thousand, in families of six the rate is 267 per thousand, and in families of eight it is 291 per thousand."

To prevent the suggested fallacious and erroneous interpretation of these statistics, it should be pointed out that they represent a survival of three and one half from each family of four children, four and two fifths from each family of six, and five and two thirds from each family of eight, indicating a net gain in numbers to the community from larger families, and constituting, therefore, in reality an argument for the desirability of increasing rather than decreasing the number of children.

## BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, May 16, 1911, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 36, scarlatina 35, typhoid fever 8, measles 236, smallpox 0, tuberculosis 68.

The death-rate of the reported deaths for the week ending May 16, 1911, was 19.45.

BOSTON MORTALITY STATISTICS. — The total number of deaths reported to the Board of Health for the week ending Saturday, noon, May 13, 1911, was 264, against 202 the corresponding week of last year, showing an increase of 62 deaths, and making the death-rate for the week, 19.98. Of this number 138 were males and 126 were females; 252 were white and 12 colored; 166 were born in the United States, 93 in foreign countries and 5 unknown; 57 were of American parentage, 169 of foreign parentage and 38 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 28 cases and 3 deaths; scarlatina, 35 cases and 2 deaths; typhoid fever, 4 cases and 0 deaths; measles, 238 cases and 5 deaths; tuberculosis, 82 cases and 20 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 42, whooping cough 9, heart disease 25, bronchitis 2. There were 22 deaths from violent causes. The number of children who died under one year was 45; the number under five years, 79. The number of persons who died over sixty years of age was 62. The deaths in hospitals and public institutions were 110.

APPOINTMENT OF DR. BREARTON. — It was announced last week that Dr. Edward J. Brearton, of Dorchester, has been appointed as assistant to Dr. Arthur H. Davison, examining physician to the Boston Department of Public Works.

Bequests to Waltham Hospitals. — The will of the late Charles H. Houghton, of Waltham, Mass., which was allowed last week before the Middlesex Probate Court, provides that the residuary estate, which it is estimated will amount to $14,500, shall be divided equally between the Waltham Hospital and the Waltham Baby Hospital.

Ringworm Epidemic at Clinton. — Report from Clinton, Mass., states that an epidemic of ringworm has appeared in one of the local schools. There are said to be at present thirty-two cases of the disease. The school building has been fumigated and all infected pupils are quarantined at their homes.

A Memorial Hospital at North Conway, N. H. — The trustees of the New Memorial Hospital at North Conway, N. H., have issued invitations for the opening of the hospital on Thursday, May 18. Addresses are expected from Governor Bass, of New Hampshire; from Dr. Charles W. Eliot, and from Dr. Arthur T. Cabot.

Metropolitan Dental Hospital Association. — The first dinner of the Metropolitan Dental Hospital Association, held in Boston on Tuesday evening, May 9, was attended by forty members. Dr. F. S. Belyer, the principal speaker, described the history and work of the society, which, since its organization in 1909, has provided free dental treatment for 2,500 poor children of this city. The officers of the association are Dr. J. W. Werner, president, and Dr. Sergius Crosby, secretary.

Nomination of Dr. Mullowney. — Last week the mayor of Boston nominated Patrick H. Mullowney, M.D.V., at present chief of the dairy inspection bureau of this city, to the position left vacant on the Boston Board of Health by the death of Mr. Frederic O. North, in July, 1910. Dr. Mullowney was born in Boston in 1870, studied at Boston College and received his veterinary degree from Harvard in 1891. His appointment has not yet been confirmed by the Civil Service Commission.

Protection of Foodstuffs in Boston. — In recent issues of the Journal we have made various comment on the attempt of the Boston Board of Health to enforce its regulation relative to the protection of foodstuffs exposed for sale in this city. During the past week, it is said, the mayor has requested the members of the Board personally to visit the markets on Saturday afternoon and evening, to determine whether or no it be really desirable to insist on this enforcement, in view of the hardship it is alleged to cause to dealers. In spite of this intervention, there has as yet been no announcement by the Board of intention on its part to desist from the action which it has advisedly taken.

Appointment of Mr. Whipple as Professor of Sanitary Engineering. — It was announced on May 11 that Mr. George Chandler Whipple, of New York City, has accepted an appointment as professor of sanitary engineering at Harvard College. He was born at New Boston, N. H., on March 2, 1862, and graduated from the Massachusetts Institute of Technology in 1889. For eight years he served as chief of the Biological Laboratory of the Boston Water Works at Chestnut Hill. Subsequently he went to Brooklyn, where he had charge of the investigation of water supply for the new metropolis of Greater New York. He is a member of many scientific and technical societies, and is recognized as an authority in public sanitation.

Plans for New Malden Tuberculosis Hospital. — It is reported that last week, on request of the Malden Medical Society and the Malden Associated Charities, the finance committee of Malden, Mass., voted to recommend the appropriation by the local city government of $12,000 for the erection of a new tuberculosis hospital to accommodate twenty-four patients. This project has been under consideration for several years. The plans provide for a wooden building to be located near the Malden Contagious Hospital. One heating plant will be used for both institutions. "The main building will be two stories high, containing the kitchen and laundry in the basement, administration offices and dining-rooms for nurses and patients on the first floor and seven rooms for nurses and the matron on the second. On each side of the main building there will be a one-story wing, one for men and one for women, each containing twelve beds. The plans are somewhat similar to those of the Somerville hospital."

Two Recent Cases of Leprosy. — In last week's issue of the Journal we chronicled the discovery of a case of leprosy at Pawtucket, R. I., and the attempt of the health authorities of that state to obtain permission from the Massachusetts State Board of Charity to have the patient received at the leper colony on Penikese Island. This request has been denied, and the

boy has since remained in quarantine at his own home, pending such arrangements as can be made for his permanent care elsewhere. Meantime, during the past week, there has been reported in Boston another case of leprosy, in the person of a Sicilian woman, forty-three years of age, who has been resident in this city four years. She has been removed temporarily to the city detention hospital, and the house where she was living has been fumigated. Despite the desirability of rigid precautions to prevent the spread of leprosy, the popular dread of it as an almost supernatural evil is quite incommensurate with the actual risk of its extension. The terror with which it is regarded is largely a survival of scriptural tradition and medieval experience.

NEEDS OF THE INFANTS' HOSPITAL. — The new building of the Infants' Hospital, near the Harvard Medical School, is making rapid progress towards external completion. Only the outer walls can be finished at present, however, since a considerable further sum of money is needed for the interior construction, equipment and future maintenance of the institution. It is earnestly hoped by those interested in the work of the hospital that this sum may be raised at an early date, in order that the erection may be continued and the building opened as soon as possible. On Wednesday of next week, May 24, a meeting will be held at the Harvard Medical School to consider the financial needs of the institution and ways and means of meeting them. Addresses are to be made by President Eliot, President Lowell, Bishop Lawrence and Dr. J. Collins Warren. It is to be hoped that this meeting may be well attended and that the friends of public philanthropy may be induced to contribute as liberally as they can to this valuable and beneficent medical charity.

TRIENNIAL CATALOGUE AND DIRECTORY OF THE MASSACHUSETTS MEDICAL SOCIETY. — The Massachusetts Medical Society publishes this week its Triennial Catalogue and Directory dated Jan. 1, 1911. This catalogue contains for the first time the street and number of the office addresses of the Fellows, besides giving, as in the past, the residences of the Fellows and the year in which each joined the society. The Fellows are enrolled in the District Societies, as always, according to their legal residences, but because of the growing practice, made possible by the automobile and other improved means of transit, of physicians living in one place and having their offices in another, there is a movement on foot in the society to permit members to elect with which District Society they will be affiliated. Special pains have been taken to have this directory accurate, but as the office addresses appear for the first time, there may have been some misunderstanding on the part of the Fellows and the residence addresses may be given instead of the office addresses in some instances.

The local list of Fellows has been much improved over past catalogues by the omission of the post offices in the state where no Fellows reside and by inserting under the heading of each city or town the subdivisions or post offices included in that city or town and by listing separately these subdivisions. For instance, West Newton appears now under W. instead of under Newton. From the statistical tables it appears that the society has now 3,332 Fellows as against 3,223 Jan. 1, 1908.

## NEW YORK.

TRAINING SCHOOL FOR DOMESTIC NURSES. — A feature of the new Union Hospital in the Bronx will be a training school for nurses which, like the nurses' school that for some time past has been in successful operation in Albany, is designed to furnish efficient nurses for persons in moderate circumstances. The length of the course of training, which has not yet been definitely fixed, will probably be six months, and, in any event, will not exceed one year, and, in order to distinguish the graduates from those of schools in which a full course of two or three years is given, they will be termed, not trained nurses, but domestic nurses. The rate of compensation they will be allowed to charge will be about $12 a week. The school will have the advantage over the similar one in Albany of being conducted in connection with a large general hospital, the Albany institution being on an independent basis. This new departure in hospital training schools will be watched with much interest, and it would seem quite probable that the plan may be adopted by some other hospitals.

VITAL STATISTICS FOR MARCH. — The State Department of Health reports that in March the number of deaths in the state reached a total of 14,227. The only other months in which the mortality previously amounted to as much as 14,000 were March, 1904, and March, 1910. This excessive death-rate is attributed largely to influenza, and in the first three months of the year the number of deaths from all causes exceeded those in the first quarter of 1910 by 1,300.

On the other hand, the high mortality in the state at large during March was offset by the large number of births reported in New York City. In the latter the deaths were only two thirds the number of births; so that while in the rest of the state the deaths slightly exceeded the births, in the city of New York there was a gain in native population of 4,617.

Tuberculosis Preventorium in New Jersey. — In furtherance of the plans for the full development of the Tuberculosis Preventorium in New Jersey, contracts have just been let for the erection of four fireproof dormitories, an administration building and a power plant on the hundred acres donated by the Arthur Brisbane estate, in the woodlands near Farmingdale, and it is in contemplation to construct two additional buildings as soon as the necessary funds have been secured. Adjoining this tract is the Brisbane stock farm of two hundred acres, on which the preventorium has a twenty-five-year lease, so that abundance of fresh air is assured for the inmates. The estimated cost of the six buildings now contracted for, which are designed to accommodate 130 children, is $100,000, and the total amount of the building fund is at present $102,000. Of this, $50,000 has been given anonymously through Mrs. J. Borden Harriman, first vice-president of the Preventorium; Nathan Strauss has given another $50,000, and Jacob H. Schiff and Felix M. Warburg have each subscribed $1,000. Since its removal from Lakewood, where it was started by Mr. Strauss in the Cleveland cottage, the work of the institution has been carried on at the farmhouse on the Brisbane estate, and up to the present, some 250 children have been treated there.

Health Statistics. — The weekly reports of the Health Department show that during the month of April the mortality in the city represented an annual death-rate of 17.54, as against 17.73 in March and 17.56 in April, 1910. The corrected death-rate, excluding non-residents and infants under one week old, was 16.51. Among the diseases which showed a diminished fatality were the following: The weekly average of deaths from typhoid fever declined from 6 in March to 4.75 in April; the weekly average from diphtheria and croup, from 35.5 to 34.75; from influenza, from 16.25 to 11.25; from epidemic cerebrospinal meningitis, from 7 to 5.75; from diarrheal diseases, from 64.75 to 63; from diarrheals under five years of age, from 62 to 58; from organic heart diseases, from 165.25 to 156.75; from cirrhosis of the liver, from 29.25 to 22.25; from Bright's disease and acute nephritis, from 128 to 124.75; and from puerperal diseases, including septicemia, from 16.75 to 13.5. Among the diseases in which there was an augmented mortality were the following: The weekly average of deaths from scarlet fever increased from 29 to 32.25; from whooping cough, from 7.25 to 8.75; from pulmonary tuberculosis, from 182.75 to 195.75; from pneumonia, from 166.25 to 172.25; from apoplexy and softening of the brain, from 24.75 to 28.25; and from appendicitis and typhlitis, from 10 to 14.75.

6. Trimble, W. B. *Impressions as to the Value of Salvarsan.*
7. Ohlbaum, J. *An Unusual Case of Placenta Previa.*

1. Watters and Eaton report thirty-five cases of typhoid fever, treated with typhoid vaccine. The initial dose was generally between twenty and thirty million bacilli and subsequent doses were a little smaller. The more serious the clinical symptoms the smaller the dose employed. No aggravation or injury of any kind was demonstrable as a result of any inoculation. The writers conclude that vaccines properly used are innocuous in typhoid fever, that they reduce mortality, shorten the duration of the disease and render relapse less liable. In one case, after a single inoculation, the temperature fell by crisis and convalescence was steady and uninterrupted. [L. D. C.]

5. Herb protests against the routine giving of drugs before anesthesia. In certain cases only is it an advantage. As a routine it should be condemned. Alarming respiratory depressions may result from the use of morphia or scopolamin before ether or chloroform. Pupillary reflexes are often disturbed after morphia or atropin so that the degree of anesthesia is obscured. In mouth operations this practice is especially to be condemned as the reflex excitability of the air passages is abolished, and thus the retention or aspiration of blood is favored. Morphia often increases the post-anesthetic vomiting.

8. Hess, writing of the subsequent health of children who drank milk in which tubercle bacilli were demonstrated, states that of eighteen children, all but one remained free from active tuberculosis during a period of supervision of three years; this one developed tuberculosis of the cervical glands, from which a bacillus of the bovine type was cultivated. From animal experiments he concludes that the chance of infection through milk depends not only on the number of bacilli ingested, but also on the frequency of exposure to small infections, for a quantity of bacilli which was insufficient to produce tuberculosis in guinea-pigs when given in one dose, suspended in milk, was able to incite tuberculosis when fed in twenty-five to thirty doses on as many days. Tubercle bacilli in butter as well as in milk are a menace to health.

9. Payne points out that in a large percentage of cases of uterine fibroids there are present symptoms of cardiovascular disturbance. The size of the growth has no relation to the severity of the cardiac disturbance; symptoms have been apparent while the growth was still small. In some cases of lost cardiac compensation associated with fibromyomata, the symptoms are materially benefited by removal of the growths, but in some cases are so severe as to result in sudden death following operation.

1. Cushny's article is the result of studies of patients with heart disease treated with digitalis and other drugs in Mackenzie's clinic. The action of digitalis has been described ever since its investigation by Traube as, in part, inhibition from the medulla and, in part, direct stimulation of heart muscle. The ventricle is more affected by the direct muscular action, and the auricle more by the central inhibitory action. As a result of his own and of Mackenzie's studies, Cushny discusses separately two groups of heart cases; first, those in which the dominant rhythm originates at the normal point, and, second, those in which the rhythm originates abnormally, as in cases of "absolute" or "perpetual" arrhythmia. In cases of the first class the beneficial effects of digitalis and its allies were less striking than in those of the second class. The inhibitory effect (slowing) was obtained in only about 30%, sometimes associated with sinus irregularity or partial heart block. The muscular effect in increasing contractility and tone could not be directly measured, but was inferred to be present in cases where clinical improvement occurred without slowing. Extrasystoles and sometimes pulsus alternans were induced. In the second class of cases with auricular fibrillation and absolutely irregular ventricles, improvement under digitalis was much more marked. The pulse was slowed in 90% of the cases with improvement in symptoms, although the heart remained irregular. This slowing was attributed to a partial blocking of the bundle of His, "relieving the ventricle from continual bombardment with impulses from the auricle," an inhibitory effect which was prevented if atropine was given. The desirability of obtaining drugs which have only the inhibitory or only the muscular action is emphasized. Aconite and aconitine for the former and helleborein for the latter have been tried, but are not satisfactory. The best effects of digitalis and strophanthus are obtained only by the largest doses that can be given without causing gastric or intestinal symptoms.

3. Wiggers has carefully reviewed the results of experimental work as to the functions of the pituitary gland and the actions of its extract. The pituitary gland is made up of an anterior and a posterior portion, the two differing in development and in structure. Extirpation experiments seem to have shown that the gland is necessary to life, and that the essential function, probably performed through an internal secretion, resides in the anterior lobe. It has been impossible, however, to obtain extracts from the anterior lobe which exert any physiological action. The posterior lobe, however, yields extracts whose action has been studied by a number of investigators, including the author. The chief effects of these extracts are (1) peripheral constriction of blood vessels with increase in blood pressure; (2) slowing and depression of heart action; (3) increase in urinary secretion; and (4) inhibition of flow of pancreatic juice.

4. Thomas' article disputes the teachings of Codman, that subdeltoid bursitis with adhesion is the common cause of stiff and painful shoulders with loss of power in the arm. Thomas describes evidence which has led him to believe that the true condition is a peri-arthritis from tears of the axillary portion of the shoulder-joint capsule.

9. Walsh, from a study of sixty-seven cases of pulmonary tuberculosis with large lesions, followed over a sufficiently long period to justify positive statements as to their results, concludes that lesions involving the whole of one lobe of the left lung usually give better results than lesions of the same size in the right lung. One reason for this appears to be that the large lesion on the left more frequently represents the secondary development in a somewhat resistant case. Lesions involving an amount of lung tissue the size of the left upper lobe are said to give a better prognosis when the opposite side shows a chronic healed lesion.

3. The presence in the throat of apparently healthy individuals of organisms morphologically typical diphtheria bacilli makes the "virulence test" of especial interest and value. The authors recommend the following technic. The organisms presenting the morphology and staining reaction of diphtheria bacilli are planted, isolated and grown in alkaline sugar broth for forty-eight hours at 37.5° C. Guinea-pigs are inoculated subcutaneously with 0.5% of body weight of this unfiltered culture. Should death not result in four to six days the organism is pronounced non-virulent. Should the pig die, the same lethal dose is mixed with 250 units of antitoxin and injected in the same way into another animal. Should this latter die, the diphtheria bacillus is considered not responsible for either of the fatal issues. Should it survive, the organism is pronounced virulent.

4. Tunnicliff finds that in mild cases of pneumonia the phagocytic power of the blood is increased; that in mild cases of scarlet fever it is unchanged; and that in severe cases of either infection it is diminished at the height of the disease. [L. H. S.]

12. JACK, W. B. *Three Cases of Peroneal Paralysis.*

1. Eve briefly sums up the so-called surgical treatment of Hodgkin's disease by the statement "Let it alone."

2. Hall gives a careful study of five cases of Hodgkin's disease with special reference to the peculiar intermittent fever often associated with it. He does not agree with Musser's conclusion that the disease is probably a glandular tuberculosis.

3. Rolleston discusses lymphadenoma, or Hodgkin's disease, in a general way as to its etiology, relation to tuberculosis, pathology and symptomatology.

4. Edgecombe has made a study of a number of patients who suffer from no particular disease, but complain of general slackness and want of tone and in whom the blood pressure is abnormally low. Improvement in their symptoms is always accompanied by a rise in pressure. He has taken the pressure at various periods, before and after rising, before and after physical and mental work, food, excitement and worry. He has studied the effects of altitude, alcohol, constipation and aperients, caffeine, tobacco, digitalis, pituitary extract, glycogen and hydrotherapy. Of the drugs, pituitary extract was most potent, with caffeine next.

9. Jordan describes "Lane's ileal kink" as a not uncommon phenomenon in general enteroptosis in which there is a kink in the intestines at this point, owing to the prolapsed condition of the rest of the gut. It rarely occurs alone, but is merely one feature of a general enteroptosis. He describes the demonstration of this by means of x-ray after the patient has had a large dose of bismuth carbonate. [J. B. H.]

10. Obermayer, F., and Popper, H. *Uremia.*
11. Holzknecht, G., and Olbert, D. *Atony of the Esophagus.*

1. Senator, after reviewing other experiments in which it was demonstrated that a mechanical blocking of the renal circulation is not the sole cause of increased arterial blood pressure, contributes a similar experiment with like conclusion. Into one of the branches of the renal artery in a cat 1.5–2.0 ccm. of a solution of warm liquid paraffine was injected very slowly. This procedure as shown by subsequent microscopic examination produced multiple emboli in glomeruli and capillaries. In spite of this increased peripheral resistance in renal circulation, no increase of pressure in the systemic circulation was produced. The author believes that we must look rather outside of the kidney for the cause of increased blood tension in chronic nephritis; that either overacidity of glands giving origin to substances having pressor effect or lack of control of these same glands — adrenal, pituitary, etc. — by supposed "hormones" from the kidney is a likely field of investigation.

2. Laache reports four cases of acute hemorrhagic encephalitis; two were accompanied by venous thrombosis, one was associated with old cysts of softening, the fourth occurred in epilepsy. No microscopic organisms were found in the brains of any. The etiology in all was obscure.

7. Twenty-three cases of aortic disease, supposedly of syphilitic origin, are analyzed. This condition comes on in mid-life, five of his cases being between thirty and forty years of age, occurring anywhere from six to forty-one years after exposure. Symptoms, which should be commonly the first evidence of the condition, are of less duration than in other forms of aortitis; in fact, seven of his syphilitic cases of broken compensation gave a history of circulatory disturbance of only one-half year, and death supervened in some shortly after symptoms had first appeared. Early to be noted are slight cyanosis, mild icterus, hypochondriasis, melancholia and even hallucinosis in the luetic form, not to be found in other varieties.

Albuminuria was not usually present, contrary to findings in arteriosclerotic cases. The Wassermann reaction was positive in twenty-one of the twenty-three cases. It is suggested that syphilographers look inside the body as well as outside for evidence of syphilis and thus more frequently discover aortic syphilis in its early stages, at which time it could be treated with greater success.

The weak part of the paper lies in the diagnosis of the condition, the history of the case and a positive Wassermann reaction frequently deciding in favor of luetic origin. Only five cases came to autopsy, and in none is mention made of the finding of spirochetæ.

8. Groedel concludes that changes in size and shape of the heart are caused solely by respiratory variations. [J. B. A.]

4. *Pascal. *Dementia Præcox.*
5. Braillon. *Diabetic Pleurisies.*

2. Tommassi describes a form of subacute rheumatism under the heading of tuberculous rheumatism. These cases, which are to be distinguished from "surgical tuberculosis," present a polyarthritis, showing slight swelling and pain, which is transient in character. The chief point of differentiation from acute polyarthritis is the lack of the cardinal signs of inflammation. Unfortunately many of the author's cases have remained unproved.

4. The author gives a very detailed account of dementia præcox, as regards its various character, symptomatology, evolution, pathology, etiology, diagnosis, prognosis and treatment. Many of the early cases are escaping diagnosis and, accordingly, the benefits derived from thorough treatment. [L. H. S.]

## Miscellany.

### OPTOMETRY IN OTHER STATES.

From time to time, in issues of the Journal, we have made editorial comment on the repeated introduction before the Massachusetts State Legislature of the so-called "optometry bill." Similar bills have been introduced before the legislatures of other states. It is reported that these bills have been defeated in Alabama, Colorado, Connecticut, Missouri, South Carolina and Texas. In Illinois, New Jersey, Ohio and Pennsylvania they are still pending, but their defeat is expected. In Massachusetts the bill has been reported favorably by a majority of the Committee on Public Health, to which it was referred. This action on the part of the committee is disappointing. It cannot be too urgently hoped that the recommendation of the minority, Drs. Grainger, Gifford and Pattee, may prevail.

In connection with the campaign for optometry in various states, it is instructive to note the history of the measure in Alabama. In this state the bill was passed by the legislature, through misapprehension of its intent, but was vetoed by the governor. In the *Journal of the American Medical Association* for May 6 is printed his veto message, which, for its clear statement of the issues involved, seems to deserve republication:

*To the Senate:* I herewith return Senate Bill No. 151 without my approval.

This bill proposes legally to organize or establish in this state a new occupation or profession, to be known as optometry, based on the science of optics as applied to the eye.

As I understand it, an optometrist is in reality an optician, and an optician has always been considered a tradesman, and he is not required or expected to have a scientific medical knowledge required by law of the oculist, whose profession authorizes him to treat the eye medically.

Inasmuch as the field of the optometrist constitutes a part of the broad field of the science of medicine, a part already occupied by regularly educated and licensed physicians, known as oculists, it becomes a question worthy of investigation and study as to the wisdom of permitting territory belonging legitimately to one profession to be invaded by persons who are not, and do not claim to be, equipped for membership in that profession. As all know, the eye is a very delicate and important organ of the body. Consequently, to deal with it intelligently there is required a thorough knowledge of not only its optics, but its anatomy, physiology and diseases. While optometrists proposed to deal only with the optics of the eye, to draw the line that separates the optics of the organ from its diseases must require a thorough knowledge of everything that appertains to the eye; that is, of its optics, anatomy, physiology and its diseases.

A man who is familiar with only one part of the subject would necessarily often be unable to determine where his domain begins. Just as a physician who understands only the anatomy, physiology and diseases of the eye would not be in a position to deal with its optics, so a person who only understands its optics would not know where its diseases begin. That is, the entire subject seems to be so closely correlated as to render it practically impossible to draw a line of demarcation between its parts and assign one part to persons who do not claim to study or understand the whole. If this be true, it becomes a serious question as to the good policy of authorizing persons by law to occupy a field, the limits of which they cannot define. A class of men, known as opticians, has long existed. The duties of these consist in grinding glasses and filling the prescriptions of oculists. This relation corresponds with that sustained by druggists and physicians, and it would seem to be the wisest policy to insist that these relations be maintained. To permit an optician to usurp the rights of an oculist, who is at the same time an educated physician, would be quite as irregular as to permit a druggist to usurp the rights of a physician in the treatment of diseases of patients.

I am informed that bills similar to this have been introduced in many legislatures, inspired, perhaps, by some large manufacturing establishments for the manufacture and sale of glasses. It is easy to see that conferring a high-sounding title on men engaged in a trade would tend to exaggerate their importance and skill in the minds of the public.

In vetoing this bill I am not d priving opticians or persons dealing in glasses of any rights that legitimately belong to them.

If such a law is enacted, it would, in my opinion, be an infringement on the already existing laws regulating the practice of medicine in this state. I therefore recommend that any applicant for the practice of optometry be required to undergo the same examination as that of any specialist who proposes to practice medicine in his selected specialty.

I am informed by physicians of the highest authority and by men who by lifelong study have thoroughly acquainted themselves with the eye and its diseases, that the legislation sought in this bill is extreme, and I am also informed by the State Board of Health that only a thoroughly equipped and licensed physician should be permitted to enjoy the privileges intended to be conferred on optometrists by this bill.

It will be noticed that it is intended by this bill that the opticians of the state shall have exclusive control of the officers provided for in the bill, and I am informed that if there is a department created by legislation akin to that sought by this bill it should be placed under the control of the State Board of Health, or of regularly licensed and educated physicians.

A bill similar to this was presented in 1907 to Governor Hughes, of New York, and was vetoed by him on this very ground.

The eye is too delicate and valuable an organ to be made the subject of any experiment whatsoever; and if there is to be such a science as that of optometry, I fear that it is yet too near to its inception to be given the power contemplated in this bill, which is returned to you without my approval.

Emmet O'Neal, *Governor.*

## Correspondence.

### TINCTURE OF IODINE AS AN ANTISEPTIC.

Fort D. A. Russell, Wyo., May 9, 1911.

*Mr. Editor:* The very delightful letter of your Paris correspondent "S.," in your issue of the 21st inst., on the antiseptic properties of iodine, hints at a more extended use of the tincture in the future.

In the vast amount of literature which has already accumulated in the last eighteen months on iodine there seems to be an unending repetition of its use as an antiseptic on the skin and surface wounds. Let me once and

for all grant this fact, which is as well established as that sugar dissolves in hot tea, and pass on with "S." to its more important uses.

The possibilities which your correspondent foresees and the cases he reports are marvelous. They have been seen and are accomplished facts on this side of the Atlantic. The treatment of tonsillitis with tincture of iodine has become routine with me and it is one which I employ in all acute inflammatory conditions of the throat and nose, even diphtheria.

A Bier's bandage is applied about the neck with sufficient compression to cause general capillary suffusion of the face. The tonsils and pharynx are painted with tincture of iodine twice daily and one teaspoonful of the tincture in one quart of normal salt solution is used frequently as a nasal spray and gargle. When I can see cases within the first twenty-four hours after the initial symptoms I expect a cure in three days. They never go on to suppuration. Chronic enlarged tonsils shrink somewhat under this treatment. Experience shows that it is not necessary to mop the throat dry before applying the tincture.

In making the iodine salt solution it is necessary to use common salt, as the commercial saline tablets contain chemicals which neutralize the iodine.

The treatment of gangrene from frost bite has made a wonderful advance with the use of this solution, which depends in part for its therapeutic power on its osmotic property. Enveloped in a saturated wet dressing of iodine salt solution, we observe first no odor of gangrene; second, the process becomes stationary at once and, third, feeble tissue is enabled to regain vitality, thus saving more tissue. I have been delightfully surprised in two cases of frost bite of the toes, where experience had led me to expect complete loss of the toes, to behold the apparently gangrenous tissue become horn-like and finally come off like a glove finger, leaving pink toes with new nails.

The treatment of fistula in ano has always been tedious; the pathological condition, the septic location, tend to make the condition most rebellious. I have been delighted to see a case of the internal, incomplete variety, after the usual incision and curettement, proceed to healthy granulation and complete recovery in six weeks under daily mopping with tincture of iodine. The pain of the application was slight and lasted but a few moments for the first few applications. The patient was able to resume his usual duties at the end of two weeks.

As an eyewash for conjunctival and blepharal infections, as an irrigation in otitis media after perforation, or for acute or chronic cystitis, as an injection in tubercular bone fistulas, as an application to burns or bullet wounds, the iodine salt solution is ideal and does the work. Goelet and Dannreuther report wonderful results with a similar solution in female gonorrhea.

Tincture of iodine is the long-desired safe antiseptic for abdominal surgery. This epoch-making discovery the writer first had the honor of demonstrating and reporting. The technic in general is as follows: The patient may or may not be prepared by previous dieting, rest in bed and stimulants. The treatment of emergency cases has shown the writer that these preliminaries are not so important as he once thought they were.

The instruments are boiled if possible. If there be no time, they are wiped off with tincture of iodine. The ligatures are dropped into the tincture at the time that the anesthetic is commenced. The site of the incision and the surgeon's hands are mopped with the tincture of iodine. Pure tincture of iodine may be used with safety on the peritoneal surface of any abdominal organ and is most efficacious in inflammatory conditions, such as pus tube or appendicitis, since it is safe in bactericidal strength and does not cause adhesions.

The writer advocated in the *New York Medical Journal* of Feb. 11, a new technic in the treatment of suppurating appendicitis which tincture of iodine alone could have made possible, as no other antiseptic is tolerable on the peritoneum in bactericidal strength.

Although the therapeutic test of the antiseptic power of iodine has been sufficiently convincing in the light of clinical results, we need no longer confine ourselves to empiric grounds to prove it. The published report of Drs. Seelig and Gould in the *Journal of Surgery, Gynecology and Obstetrics* for March, 1911, on "Osmosis in the Action of Antiseptics," proves conclusively that iodine and alcohol combined have a most powerful osmotic property far beyond that of any other antiseptic either alone or in watery or alcoholic solution; hence the singular efficacy of the tincture of iodine to penetrate the deeper tissues and exert its antiseptic virtues. Experiments with living and dead membranes show that this combination penetrates in a few minutes where some do not for two hours, thus proving conclusively that the use of any of these antiseptics except iodine and alcohol for immediate sterilization of hands or skin is as futile as attempting to cook a roast of beef in five minutes. Yet with all these assurances and reports there will be some even after we are dead who will believe that permanganate of potassium and oxalic acid followed by a dip in 1–1000 bichloride will instantly sterilize the skin of the hands and will prefer iodoform because it is *said* to liberate iodine in the body fluids — and besides, they have always used it. I am,

Very truly yours,

FRANK THOMAS WOODBURY, M.D.

## RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, MAY 6, 1911.

| CITIES. | Reported deaths in each. | Deaths under five years. | CITIES. | Reported deaths in each. | Deaths under five years. |
|---|---|---|---|---|---|
| New York | — | — | Waltham | 7 | 0 |
| Chicago | 682 | 177 | Brookline | 7 | — |
| Philadelphia | 576 | 145 | Chicopee | 10 | 4 |

## SOCIETY NOTICE.

AMERICAN SURGICAL ASSOCIATION. — The American Surgical Association will hold its thirty-second annual meeting at Denver, Colo., June 19, 20 and 21.

CHARLES A. POWERS, M.D.,
*Secretary.*

## RECENT DEATHS.

GAY, WILLIAM FREDERICK, M.D., M.M.S.S., died at Boston, May 12, 1911, aged forty-two years.

DR. SAMUEL E. HOLTZMAN, of New York, died suddenly from cardiac disease on May 8, at his summer residence at Ocean Grove, N. J., at the age of seventy-three years. He was born in Winchester, Va., and early in life removed to Indiana. At the time the Civil War broke out he was a hospital interne in New York City, and he served throughout the war as a surgeon in the army. Some twelve years ago he became incapacitated in consequence of a fracture at the hip-joint, and since then his winter home has been with a married son at Hastings-on-the-Hudson.

## Original Articles.

# THE OCCURRENCE OF INFANTILE PARALYSIS IN MASSACHUSETTS IN 1910.

## Reported for the Massachusetts State Board of Health.

BY ROBERT W. LOVETT, M.D., BOSTON,
AND
PHILIP A. E. SHEPPARD, M.D., BOSTON.

The last year has been one of considerable progress in our knowledge of infantile paralysis. The disease has been widespread in the United States, and twenty-three states have made the disease reportable, and several state boards of health have taken up the work of investigation. The clinical study of cases has become more accurate and careful, and the importance and frequency of abortive cases has been much more fully recognized.

Three certain interesting contributions to our knowledge are as follows:

Osgood and Lucas found an active virus in the naso-pharyngeal membrane of one monkey, who had recovered from the acute attack five and one-half months afterward and in another six weeks afterward. This virus was sufficiently active to cause paralysis in a first and second generation of monkeys into which it was injected.[1]

The second contribution is from Flexner and Clark.[2] It has been previously shown that if hexamethylenamin is administered by mouth, its presence can be detected in the cerebrospinal fluid. Flexner and Clark showed that if the drug be given by mouth and its use continued after its presence in the spinal fluid can be detected in monkeys, and if such animals are subsequently inoculated either subdurally or by the intracerebral route, the paralysis is in a certain proportion of cases delayed or prevented. But successful results by the drug have so far been obtained in inhibiting infection and not in restraining an already established infection. In other words, there is as yet an absence of experimental evidence to show that the drug is of much use when the disease has begun.

A third contribution by Anderson and Frost[3] is as follows: It is only very recently that it has been found possible by a laboratory method to throw back light on whether a suspicious case occurring in the past may or may not have been abortive infantile paralysis. It is possible by means of neutralization tests to determine this matter by mixing the blood serum of the recovered case with the filtered virus, and injecting the mixture into a monkey, the serum of recovered cases having the power of neutralizing a certain amount of the virus.

By a study of the changes in the cerebrospinal fluid in monkeys preceding the paralysis, a forecast of the probable changes in man was worked out and paralysis predicted in a human case where a lumbar puncture was done early. The case is reported by Frissell.[4] The changes are the following: At the height of the lesions in the meninges it has been found in monkeys and confirmed in a human case that the cerebrospinal fluid is slightly turbid or opalescent and contains an excess of protein. There is a large increase of white cells both poly- and mono-nuclear. The fluid may in some cases be distinctly turbid, and polynuclear cells may predominate. Paralysis occurs at the height of these changes and then the changes described in the fluid begin to disappear.

In the matter of etiology more attention has been paid to dust, and the data reported by Hill[5] are suggestive. In Winona, Minn., there were 29 cases up to the end of July, 27 occurring on dusty streets. On Aug. 5, street watering was begun at the suggestion of the state and local health officials, and no case occurred in Winona after Aug. 12, although the greatest incidence throughout the state had yet to develop and the neighborhood outside of Winona continued to show cases. Hill quotes also three other instances in the state of a similar occurrence.

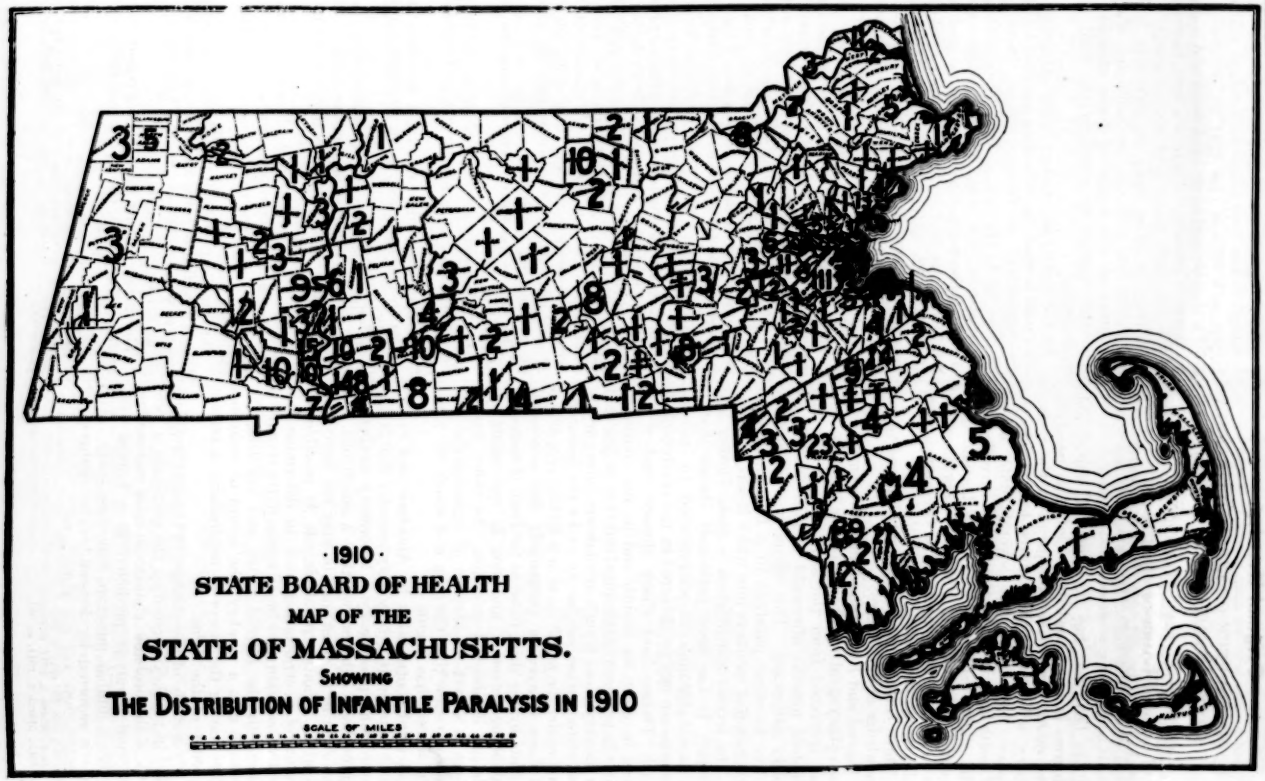
The need of quarantine is being appreciated, and the experience in Nebraska is worth quoting:[6] "We were informed that no legal provision had been made for quarantining such cases, and isolation was recommended, but, of course, could not be enforced nor could the impending Fourth of July celebration be abandoned. This celebration was well attended and shortly after cases were reported from communities previously free from the disease and having had representatives present at the celebration. From May 30 to July 4 we had in the Stromsberg territory 30 cases, while from July 4 to Aug. 3, just thirty days, we had one hundred and fifteen cases." A quarantine was declared necessary and put into effect on July 22, and after Aug. 3, there were only 15 cases in the Stromsberg territory.

The salient points in progress may be summarized as follows:

(1) A decidedly keener attitude on the part of the profession, the health boards, and legislative bodies toward the disease.

(2) The knowledge that the infection may persist in the nasopharynx in monkeys for long periods.

(3) The possibility of diagnosticating after recovery the character of abortive cases.



(4) The possibility of early diagnosis by means of lumbar puncture.

(5) The possibility that hexamethylenamin may be in monkeys at times a preventive of infection, but does not apparently control established infection.

During the year 1910 the Massachusetts State Board of Health continued for the fourth consecutive year the investigation of infantile paralysis as it occurred in the state.[7]

The disease having been made a reportable one in November, 1909, the board received notice of

·1910·
STATE BOARD OF HEALTH
MAP OF THE
STATE OF MASSACHUSETTS.
SHOWING
THE DISTRIBUTION OF INFANTILE PARALYSIS IN 1910
SCALE OF MILES

cases reported by physicians, and to them blanks were sent to be filled out and returned. Dr. Philip A. E. Sheppard and Dr. T. P. Hennelly were employed by the board to investigate the cases at their homes, to make an intensive study of epidemic centers and to see as many other cases reported as practicable. The scope and direction of the inquiry have again been supervised by an advisory committee consisting of Dr. Theobald Smith, Dr. Milton J. Rosenau, Dr. James H. Wright and Dr. John Lovett Morse, who have met at frequent intervals the secretary of the board and the members concerned in the inquiry. The legislature of 1910 generously appropriated the sum of $5,000 for the purposes of this investigation.

The data relating to the disease in the state during the year 1910 will be here presented, and later in another form will be presented those conclusions that seem warranted by a study of the disease in Massachusetts for four years, with certain general considerations with regard to the disease. The investigation will be continued in 1911 on a more extended scale, $10,000 having been appropriated for the purpose by this year's legislature.

There are three classes of cases to be reported on:

(1) The total cases reported by physicians with their location, — 845.

(2) The number of cases for which blanks were filled out, — 601.

(3) A group of cases carefully studied by the medical investigators of the board, — 200.

The groups of cases considered in various respects will, therefore, differ in number, more space in general being allotted to the 200 carefully studied than to the others.

The record of the last four years is as follows:

| | Cases. | Cities and towns with cases. |
|---|---|---|
| 1907, | 234 | 75 |
| 1908, | 136 | 47 |
| 1909, | 923 | 136 |
| 1910, | 845 | 153 |

The distribution of the cases is seen in the map, from which it will be seen that marked epidemic centers existed in Springfield and Fall River, with a suggestion of a minor epidemic center in Boston. The number of cities and towns affected was larger in 1910 than in 1909, when there were a greater total number of cases.

Deficiency Rainfall, 1904–1910, Inclusive.

| Year. | Cases in state. | Actual. | Normal. | Deficiency. |
|---|---|---|---|---|
| 1904 | | 43.81 | 45.16 | −1.35 |
| 1905 | | 37.60 | | −7.56 |
| 1906 | | 43.21 | | −1.95 |
| 1907 | 234 | 44.49 | | −0.67 |
| 1908 | 136 | 37.61 | | −7.55 |
| 1909 | 923 | 42.10 | | −3.06 |
| 1910 | 845 | 35.50 | | −9.42 |
| | | | | −31.56 |

A consideration of this table shows that for the last four years the driest years have not been attended by the largest number of cases in Massachusetts.

The comparison of the rainfall by months and the incidence of the disease shows that in 1910 August was the driest of the three summer months and also the one in which the largest number of cases occurred. August was also the month with the highest mean temperature, so that both drought and heat were at their height when the largest number of cases occurred.

Analysis of Cases Thoroughly Studied.

(200 cases in 186 families.)

| | | |
|---|---|---|
| Total number of children, | | 488 |
| Number of contemporaneous illnesses in children and adults, | | 253 |
| Number of children paralyzed, | 172 | |
| Number of adults paralyzed, | 28 | |
| | — | 200 |
| Possible abortive cases, | | 53 |

An investigation of the nearness of the affected house to railroad and highroad showed no preponderating number close to either, 15% being close to a railroad and about 60% on the highroad. The nearness to water in the 200 cases studied in and around Springfield showed 17% within one-eighth mile of the river, 35% within one-fourth mile and the rest at greater distances. Of the remaining cases in other localities, in the great majority of cases where it was stated, the house was not near the water.

### SURROUNDINGS OF PATIENTS.

*Age of house.* — The affected house was a new house, that is, less than ten years old, in 27% of the cases, and over ten years old in the remainder, and an investigation of the *sanitary condition* of the house showed, as in former years, that in most cases such conditions ranged from fair to excellent. In 74% of the cases the location was given as "dry," and as "damp" in the remainder.

An investigation of the *water supply* and *sewage disposal* showed in the great majority of cases city and metropolitan water supply and sewage disposal, so that no common factor is to be found in either of these elements which might be assigned as a possible cause.

*Dust.* — The amount of dust in affected localities was most carefully inquired into, but there is no standard of measurement and the information in the following table must be regarded as only approximately accurate:

| | Cases. |
|---|---|
| No dust, | 156 |
| Very little dust, | 124 |
| Much dust, | 123 |
| Moderate amount of dust, | 172 |
| Excessive amount of dust, | 7 |
| Not stated, | 77 |

In this connection the treatment of streets on which cases occurred was investigated. The results were as follows:

| | Cases. |
|---|---|
| No treatment, | 316 |
| Watered, | 162 |
| Oiled, | 32 |
| Watered and oiled, | 16 |
| Not stated, | 75 |
| | 601 |

*Digging* or *excavating* in the neighborhood of affected houses had been in progress in a little over 15% of 334 cases where data existed on this point.

PRESENCE OF INSECTS, VERMIN, RODENTS, ETC.

Among 185 families, 185 had insects, etc., as follows:

| | | | |
|---|---|---|---|
| Flies were present | in | 185 | families |
| Mosquitoes were present | " | 67 | " |
| Ants | " | 62 | " |
| Mice (house) | " | 60 | " |
| Bedbugs | " | 39 | " |
| Roaches | " | 29 | " |
| Spiders | " | 26 | " |
| Rats | " | 23 | " |
| Biting flies | " | 7 | " |
| Field mice | " | 4 | " |
| Fleas | " | 2 | " |
| Bees | " | 2 | " |
| Sand fleas | " | 1 | family |
| Snakes | " | 1 | " |
| Crickets | " | 1 | " |
| Squirrels | " | 1 | " |
| Leeches | " | 1 | " |

As to *insect bites*, there was no such history in 70% of 200 cases carefully investigated; a history of mosquito bites in 27% and in the remainder bites from various insects were recorded.

Any investigation as to the prevalence of an especial insect in a given locality, which is to be of much value, must be made on the spot by a person skilled in entomology, and definite conclusions cannot be based on the above table.

DATA AS TO ILLNESS IN DOMESTIC ANIMALS AND BIRDS.

Of 186 families:

| | |
|---|---|
| No animal of any kind in | 76 |
| Animals present in | 110 |
| | 186 |

Thus:

(*a*) 27 homes had 31 dogs without sickness.
50 " " 66 cats " "
39 " " about 745 hens and chickens without sickness.
11 " " 18 horses without sickness.
3 " " 3 cows " "
4 " " 4 canaries " "
10 " " 2 goldfish " "
1 home " 5 geese " "
1 " " 10 ducks " "
1 " " 10 pigeons " "

(*b*) 6 homes " 14 hens with sickness.
6 " " 6 " " "

(*c*) 4 " " 4 dogs with paralysis.
4 " " 12 hens " "

(*d*) 2 " " deaths in 2 dogs.
6 " " " " 6 cats.
8 " " " " 42 hens.
2 " " " " 2 horses.

Total, 34 homes out of 110 had illness, paralysis or death in 82 animals near the time of the human paralysis.

As to paralysis in domestic animals, a veterinary surgeon, Dr. A. W. May, was employed by the board in the autumn of 1910 to visit kennels, poultry farms, veterinary hospitals, etc., through as much of the state as possible, in order to see if the distribution of animal paralysis corresponded to that of the human disease. His report will be published separately.

Other data not given in former reports follow:

NATIVITY.

| | Cases. |
|---|---|
| American, | 315 |
| French Canadian, | 33 |
| French, | 51 |
| French American, | 5 |
| Irish American, | 65 |
| Polish, | 19 |
| Portuguese, | 13 |
| Hebrew, | 15 |
| Italian, | 11 |
| English, | 9 |
| English American, | 2 |
| Irish, | 4 |
| French-Irish, | 2 |
| Colored, | 6 |
| Swedish, | 15 |
| German American, | 6 |
| Greek, | 5 |
| Finlander, | 2 |
| Nova Scotian, | 2 |
| Scotch, | 4 |
| Austrian, | 1 |
| Bohemian, | 1 |
| Not stated, | 15 |
| | 601 |

This table is important as showing that the apparent partial immunity of the colored race may be less true than had been supposed, the relative incidence in Massachusetts in 1910 per thousand of population being in the colored race .17 and in the white .20. In order to obtain the incidence among the colored race in a community thoroughly infected, this was calculated for Springfield where, in a colored population of 1,294, there occurred 4 cases, an incidence of 3.09 per thousand, while in the white population of the same city the incidence was 1.99 per thousand.

COMMUNICABILITY.

The question of communicability is probably obscured by the existence of abortive cases. The data here presented were established with all possible care. In 200 cases there was certain direct contact with an acute case in 32 cases, indirect contact in 10, and direct contact with a possible abortive case in 4. Out of 186 families, 13 had 2 cases and 1 family had 3.

There were no lodgers in 176 families of 186 investigated in this regard, and 18 lodgers in the 10 other families.

CONDITIONS PRECEDING THE ATTACK.

*Swimming and wading.* — Out of 524 cases when the question was answered, it was stated that 15.8% of the patients were swimming, wading or paddling in water just before the attack, while the remainder were not.

In 1909, out of 150 cases, 40.8% gave such a history on account of the different locality in-

vestigated last year, which may serve as a reminder that in estimating the possible effect of etiological factors too much importance cannot be attached to investigations confined to one locality.

*Exposure to heat, cold or dampness* just preceding the attack occurred in the history of 27% of 575 cases and was absent in the rest.

An *accident, fall* or *over-exertion* was noted in 23% of 573 cases just before the attack.

### DIET.

The majority of the patients ate of several kinds of food. In the analysis of a series of 200 cases studied in and around Springfield, four babies, all under six months, were said to be fed on breast milk alone. The other data as to diet were not apparently of especial interest, many articles of food being given, from a study of which no conclusive data can be drawn.

### By Age Periods.

| | Cases. | Per cent. Approximate. |
|---|---|---|
| From birth to twelve months inclusive, | 51 | 8.5 |
| From thirteen months to twenty-three months inclusive | 65 | |
| Two years old, | 61 | |
| Three years old, | 98 | |
| Four years old, | 69 | |
| Five years old, | 51 | 65.5 |
| | 395 | |
| Six to ten years inclusive, | 93 | 80.8 |
| | 488 | |
| Eleven to twenty years inclusive, | 69 | 92.1 |
| | 557 | |
| Twenty-one to thirty years inclusive, | 28 | |
| Thirty-one to eighty years inclusive, | 15 | |
| | 600 | |

It is evident by a comparison with the table for 1909 that in 1910 a larger number of older children were attacked, the percentage of all cases from one to ten inclusive being 87.48 in 1909, while in 1910 only 80.8% of the same age were attacked.

### Mortality by Age.

| | Cases. | Deaths. | Mortality. (Per cent.) |
|---|---|---|---|
| Under one year, | 38 | 3 | 7.89 |
| One to ten years, | 451 | 39 | 8.64 |
| Over ten years, | 112 | 12 | 10.71 |
| Total, | 601 | 54 | |
| Average mortality, | | | 8.98 |

The total mortality was 1% higher than in 1909.

### INCIDENCE OF THE DISEASE.

*Sex.* — There were 331 males and 270 females affected.

*The condition of the patient preceding the attack* was given in 540 cases; in about 30% the patient had been perfectly well and in about 60% some abnormal condition existed either some time before or just previous to the attack. Malaise existed in about 20%, affection of the throat or respiratory passages in 9%, gastric or intestinal disturbance in 11% and in the remainder a variety of illnesses, the only group of significance being 10 cases where operation, wounds or sores preceded the attack. A study of the *recent illnesses in members of the same family* showed nothing of apparent importance, a moderate number of ordinary illnesses as being recorded, chiefly of the upper respiratory passages and digestive tract.

### General Features of Acute Attack for 601 Cases.

| | |
|---|---|
| 540 | cases give history of fever. |
| 487 | " " " " pain and tenderness. |
| 284 | " " " " brain symptoms. |
| 209 | " " " " retraction. |
| 95 | " " " " sore throat. |
| 2 | " " " " nystagmus. |
| 1 | case gives " " hiccough. |

*Digestive disturbance* during the attack occurred in about 75% of the cases, this disturbance being nausea and vomiting, constipation or diarrhea, with colic in a few cases.

*Disturbance of the bladder* did not occur in 73% of the cases, but retention was noted in 20% of the cases and other minor disturbances in the remainder.

### Pain and Tenderness.

| | Cases. |
|---|---|
| Pain and tenderness was present in | 469 |
| " " " " absent in | 42 |
| " " " " not stated in | 90 |
| | 601 |

### Pain or Tenderness Lasted.

| | Cases. |
|---|---|
| No pain, | 42 |
| One day or less, | 9 |
| Two days, | 14 |
| Three days, | 20 |
| Four days, | 15 |
| Five days, | 10 |
| Six days, | 6 |
| One week, | 35 |
| One to two weeks, | 41 |
| Two to three weeks, | 32 |
| Three to four weeks, | 18 |
| Four to five weeks, | 8 |
| Five to six weeks, | 4 |
| Eight to nine weeks, | 5 |
| Nine to ten weeks, | 1 |
| A few days, | 25 |
| Until death, | 45 |
| Present when report made, | 181 |
| Not stated, | 90 |
| | 601 |

### Appearance of Paralysis in Days and Weeks after Onset of Fever.

| | Cases. |
|---|---|
| Same day, | 20 |
| One day, | 31 |
| Two days, | 40 |
| Three days, | 34 |
| Four days, | 15 |
| Five days, | 11 |
| Six days, | 11 |
| Seven days, | 14 |
| Eight days, | 4 |
| Nine days, | 2 |
| Ten days, | 2 |
| Eleven days, | 2 |
| Twelve days, | 4 |
| Thirteen days, | 1 |
| Fourteen days, | 1 |

| | Cases. |
|---|---|
| Two to three weeks, | 5 |
| Three to four weeks, | 1 |
| Four to five weeks, | 1 |
| Eight weeks, | 1 |
| | 200 |

DISTRIBUTION OF EARLY PARALYSIS.

| | Cases. |
|---|---|
| One leg only, | 145 |
| Both legs only, | 146 |
| One arm only, | 44 |
| Both arms only, | 12 |
| One arm and leg, same side, | 50 |
| One arm and leg, opposite sides, | 18 |
| Both legs and one arm, | 32 |
| Both arms and one leg, | 8 |
| Both arms and both legs, | 51 |
| Ataxia (transitory), | 7 |
| Back, | 79 |
| Abdomen, | 38 |
| Neck, | 13 |
| Respiration, | 39 |
| Deglutition, | 12 |
| Intercostal, | 1 |
| Face, | 7 |
| Right face, | 31 |
| Left face, | 24 |
| Strabismus, | 2 |
| Not stated, | 32 |

Nine cases out of 200 gave a history of some *skin eruption* appearing on the chest or around the neck, or about the girdle.

In one or two such cases there was noted by the investigator a small maculo-papular rash — a faint blush underlying the area with no definite redness to base of vesicle.

PROGNOSIS.

Up to the time of assembling the board's report (a period of six months after the beginning of the epidemic outbreak in western Massachusetts) 27 cases (13.5%) out of 200 had completely recovered.

A study of the age, distribution of the early paralysis and duration of tenderness and paralysis in these cases leads to the conclusion that the early symptoms offered no means of distinguishing them from cases where the paralysis was to be permanent.

CONCLUSIONS.

The disease in Massachusetts was nearly as prevalent in 1910 as in the previous year, and affected 153 cities and towns instead of 136 as in 1909. But one must remember that a much larger proportion of cases are now recognized and reported in Massachusetts than was formerly the case, so that probably the apparently relative prevalence of the disease in Massachusetts when compared to other states, the total number of cases in the state and the apparent spread are in some measure due to the alert attitude of the medical profession of this state in recognizing and reporting cases.

A large epidemic center existed in Springfield, with 148 cases in the city and a large number in the surrounding towns, the distribution appearing to be radial from Springfield. Another epidemic center existed in Fall River, with 89 cases in the city and more or less radial distribution to contiguous towns.

It is evident that the disease has existed in all classes in the community, and not only among the lower classes, from the report on the sanitary conditions under which the patient lived, and also that it exists under all conditions of sewage disposal and with all kinds of water supply. Our researches in the last two years have failed to show an excessive amount of dust in affected localities.

The proportion of affected houses in which contemporaneous sickness, paralysis or death existed in domestic animals or birds still seems larger than one would naturally expect.

The occurrence of 6 cases in the colored race is of importance in connection with the data of other investigators, who have found the race rarely affected.

The facts given with regard to communicability are to be regarded as important, 42 such histories having been obtained in 200 cases.

No definite information as to any one factor is to be found in the antecedents of the attack, since bathing, falls, exposure to heat, overexertion, etc., are common occurrences in children of the affected age in the summer season; nor in the study of diet does there seem much of importance except for the existence of the disease in 4 nursing babies.

The fact has been commented on that the disease was a little more prevalent this year in older children than in 1910.

The study of the immediate antecedents of the attack and the early symptoms show nothing of especial present interest except the very common occurrence of pain and tenderness, and the information as to its duration is of value.

The distribution of paralysis was made by a skilled investigator in a group of cases carefully studied, and it is important to note under those conditions the comparatively frequent involvement of the back, abdomen, neck and face — a matter often overlooked.

The per cent of total recoveries from the paralysis within a period of six months and less after the attack was 13.5% in 200 cases as against a a per cent of 16.7% in a similar class of cases in 1909.

For the year 1911 the State Board of Health intends to pursue the same investigation as in the four previous years on a more extended scale, hoping by a study of the disease in one locality over a term of years to reach some conclusions as to its characteristics.

As in former years the board is under great obligations to the medical profession for their ready co-operation at all points and asks for the coming year the same ready assistance.

## ANTERIOR POLIOMYELITIS.*

### Attempts to Transmit the Disease to Monkeys by Inoculation with the Nasal, Pharyngeal and Buccal Secretions of Eighteen Human Cases.

BY M. J. ROSENAU, M.D.,
*Professor of Preventive Medicine and Hygiene, Harvard Medical School, Boston;*
PHILIP A. E. SHEPPARD, M.D.,
*Special Investigator for the Massachusetts State Board of Health, Boston;*
AND
HAROLD L. AMOSS, M.D.,
*Assistant in Preventive Medicine and Hygiene, Harvard Medical School, Boston.*

We lack definite information concerning the mode of transmission of epidemic poliomyelitis. Such information is of fundamental importance from the practical standpoint of preventing the spread of the disease. Flexner and Lewis have shown that the virus may be obtained in the nasal and pharyngeal mucosa of monkeys, and it has been assumed that the virus leaves the body in the secretions of the mouth and the nose; the mode of entrance is perhaps through the nasal and pharyngeal mucosa. This view is strengthened by the known facts in a somewhat analogous infection — epidemic cerebrospinal meningitis.

We have undertaken this work to determine whether the virus of epidemic poliomyelitis may be demonstrated in the nasal, pharyngeal and buccal secretions of patients in various stages of the disease; in convalescents; or in suspected carriers.

The methods employed were as follows:

#### COLLECTION OF MATERIAL.

The specimens were all personally obtained by one of us (P. A. E. S.). The patient was taken just as he was found without being cleaned up at all, but the usual antiseptic precautions were employed by the operator and all instruments and appliances were sterilized.

Each specimen was collected in a sterile vial. The salt solution used to wash the mucous membranes of the nose and throat was practically normal and was freshly made for each case. The instruments used were a Goodale syringe, a nasal douche, nasal forceps and applicators.

To secure the specimen the patient was seated directly before the operator and first instructed to gargle with a mouthful of salt solution which was then secured in a sterile bottle; next the nasal douche was filled with salt solution and used alternately in each nares as follows:

With the patient's head slightly tipped back, until the floor of the nares is approximately horizontal, the salt solution is allowed to flow in gently. The douche is then removed, the nares closed with the thumb and finger of the operator. The head of the patient is next brought forward as far as necessary to allow the salt solution to run out through the opposite nares (this is brought about by releasing pressure on the appropriate side), and the fluid is caught in the sterile bottle. In order to expel the last portions of salt solution, and at the same time to remove the residual mucus and nasal secretion, the patient is instructed to blow gently through the open nostril. The procedure is then repeated on the other side. The applicator, tipped with sterile absorbent cotton, is used repeatedly along the floor of the nasal cavities and gently passed back into the pharynx in order to clean up and remove those portions of mucous and nasal secretions which cannot be obtained by simple irrigation. The mouth is now either swabbed with sterile absorbent cotton, or, if the patient is old enough to understand, is instructed to chew the pledget of absorbent cotton, this being done in order to secure the saliva. If the tongue is at all coated, some of this material is wiped off as well.

The Goodale syringe, filled with salt solution, is now introduced into the mouth and passed back gently until the tip is inserted under the uvula and directed upward and forward into the pharyngeal vault, when the contents of cylinder (containing about 3 ccm. salt solution) is expressed quickly and the syringe withdrawn. The vestibules of the nasal cavities having previously been plugged with sterile absorbent cotton, the head of the patient is lowered immediately to allow the salt solution to drain into the absorbent cotton. These pledgets of cotton are added to the other secretions in the sterile bottle, and the patient is instructed to blow gently, first through one, then through the other nostril, into the collecting bottle. The applicator, tipped with cotton, is again brought into play in order to clean up the cavities still further. This process is repeated two or three times in each case until the cavities are fairly well cleared out, the end in view in every case being to secure a large amount of material with as little discomfort as possible to the patient.

#### EXPERIMENTAL TECHNIC.

The material thus collected was cooled and brought without delay to the laboratory packed in ice. It was then passed through a Berkfeld filter, warmed to about 30° C. and injected into the brain and peritoneal cavity of monkeys (Macacus Rhesus).

A small gimlet hole was bored in the skull on each side over the frontal lobes (under ether anesthesia). About 4 ccm. of the filtrate was then introduced into each cerebral hemisphere and the remainder was injected into the peritoneal cavity.

A brief account of the eighteen cases follows:

Case No. 1. F. F., age five, male, American, living in Springfield, Mass. Sanitary condition of dwelling good. No other case in the family. The boy appeared to be well developed and nourished, and the mother says was always healthy.

Acute febrile attack Sept. 25, 1910, followed by paralysis of the muscles of deglutition and vocal cords, with aphonia on the sixth day.

The general features of the acute attack were nausea and vomiting, starting on the morning of Sept. 25, and recurring at intervals during the next twenty-four hours, temperature of 103° F., restlessness and

* Report to the State Board of Health of Massachusetts, February, 1911.

wandering of mind, pain and tenderness lasting a few days in the neck muscles and right leg, sore throat and aphonia, persistent constipation.

On Sept. 13 (twelve days before the acute febrile attack), tonsils and adenoids were removed at a Springfield hospital.

The boy was first seen by one of us early in October, 1910. He was in a very nervous condition and all reflexes were exaggerated. He could swallow with difficulty, though his voice was returning. The throat was slightly injected and there was some bronchial cough.

On Nov. 5, when the specimen was secured for inoculation, he was still very nervous, and the throat symptoms persisted, but the paralysis had practically disappeared.

*Monkey (1).* On Nov. 5, 1910, 4 ccm. were injected into right brain, 4 ccm. into left brain, and 50 ccm. into peritoneal cavity. Normal recovery from the anesthesia. Never showed any suspicious symptoms, though on Nov. 11, temperature was 103.3° F. Dismissed from observation Feb. 2, 1911.

CASE No. 2. D. Y. (American born of Scotch parents), age five, living in Ludlow, Mass. Sanitary condition of dwelling good. No other case in family. Had scarlet fever and was in Springfield Isolation Hospital from Aug. 6, 1910, to Sept. 24, a period of seven weeks, during which time there were cases of anterior poliomyelitis in the same isolation hospital. During his stay there the child had a bad sore throat and several cultures were taken, all of which proved to be negative for the diphtheria bacillus.

Patient returned to Ludlow, Sept. 24, and two weeks later (Oct. 7) acute febrile attack developed, followed two days later by paralysis of right arm and both legs.

The general features of acute attack were: Nausea and vomiting, fever, 102° F., retraction of head, brain symptoms (listless and stupid), pain in head which had lasted two days, when paralysis of right arm and both legs appeared. Urine was negative. Vomiting and diarrhea accompanied the febrile attack and the diarrhea continued for several weeks, being followed finally by constipation.

On Nov. 5 (four weeks after his febrile attack) specimen was secured for inoculation. The child was still in bed with a temperature of 101° F. There was bronchial cough, the throat was slightly injected and paralysis of both legs and right arm persisted.

*Monkey (2).* On Nov. 5, 1910, 4 ccm. were injected into right brain, 4 ccm. into left brain, and 85 ccm. into peritoneal cavity. The animal recovered promptly from the operation and never showed suspicious symptoms. Nov. 10, temperature 104.8° F. Dismissed from observation Feb. 1, 1911.

CASE No. 3. V. P., age four, female, born of American parents, living in Springfield, Mass. Well developed and nourished. Sanitary condition of dwelling good. No other case in the family.

Acute attack Oct. 11, 1910, with fever, pain and tenderness along spine. Paralysis developed seventy-two hours later involving both legs.

On Nov. 5, when specimen was obtained for inoculation, the child was in good health, the walk was ataxic.

*Monkey (3).* On Nov. 5, 1910, 4 ccm. were injected into right brain, 4 ccm. into left brain, 50 ccm. into the peritoneal cavity. Monkey recovered well from the anesthesia and remained lively and apparently well. Dismissed from observation Feb. 1, 1911.

CASE No. 4. T. C. (American born of Irish parents), age eighteen, female, living in Springfield, Mass. Sanitary condition of dwelling good. No other case in the family. T. C. well developed and before onset was well nourished.

Acute febrile attack occurred Aug. 18, 1910, and the next day paralysis of both legs, both arms, back and abdomen developed.

The general features of the acute attack were sudden fever, 104° F., intense pain and tenderness in the back and lower extremities lasting six weeks, together with marked change of temperament — irritability. On the second day of attack patient voided a clear green urine with a trace of albumen.

On Nov. 5, when the specimen was taken, the paralysis of both legs and both arms still persisted, and there was slight involvement of intercostals, so that she could not cough properly. She was apathetic and weak, but had recovered in large measure her sunny disposition.

*Monkey (4).* On Nov. 5, 1910, 4 ccm. were injected into right brain, 4 ccm. into left brain, 75 ccm. into peritoneal cavity. Recovered promptly from the operation, but on Nov. 7 (two days later) was unusually quiet, did not climb and hid his face. The next day (Nov. 8) the temperature was 102.5° F., and he was placed in a separate cage. On Nov. 9, his disposition seemed changed, he did not express fear and could be approached without being excited. No paralysis; walked on four legs.

On Nov. 10, he seemed weak and dazed and temperature was 101.4° F. On Nov. 11, would not eat except when fed by hand. Pupils equal, reacted to light. Temperature, 100.4° F. Hand and wrist on right side weaker. Nov. 12, general weakness, moved in circles to the left, head and eyes turned to the left. Temperature, 98° F. Died Nov. 13, 3 P.M. Autopsy showed a hemorrhage in the right anterior lobe in the white matter, with pus in the left brain near the motor area for the arm. Cortex was markedly congested, the dura apparently normal.

CASE No. 5. R. T., age five, male (American born of Irish parents), living in Springfield, Mass. Sanitary condition of dwelling bad. Patient well developed and nourished. No other case in family.

Acute attack Oct. 6, 1910, with high fever and sore throat. Paralysis of both legs developed a week later.

On Nov. 5, when specimen was obtained for inoculation, paralysis was disappearing. Tonsils were still swollen, however, and there was some bronchial cough.

*Monkey (5).* On Nov. 5, 1910, 4 ccm. were injected into right brain, 4 ccm. into left brain, 65 ccm. into peritoneal cavity. The animal recovered promptly from the anesthetic, but the next morning did not use right arm, which hung limp. Tendency to lean towards right. Nov. 7, both the right arm and right leg were weak. Would not eat. On Nov. 9 he ate better and used right leg somewhat, but right arm was still limp. Temperature, 102° F. The condition improved somewhat, but the lameness of right arm and right leg persisted. It is most probable that the paralysis was the result of mechanical injury at the time of the operation. Dismissed from observation Feb. 2, 1911.

CASE No. 6. A. L. T., age five, male, American, living in Middleboro, Mass. Sanitary condition of dwelling good. No other case in the same family, but younger brother was sick with dysentery about the same time. Lived an out-of-door life. For a couple of weeks before onset was fussy and irritable.

Acute attack Oct. 25, 1910, with the following general features. Fever ranging from 100° to 104° F., delirium, pain and tenderness general, but more pronounced in legs, disturbance of vision and speech lasting two days. Inclined to jump and twitch. Reflexes absent. Paralysis appeared two days after onset, involving the left leg.

On Nov. 13, when specimen for inoculation was

obtained, patellar reflex was absent. Paralysis of left leg persisted. General condition improved.

*Monkey* (*6*). On Nov. 13, 1910, 4 ccm. were injected into right brain, 4 ccm. into left brain, 50 ccm. into peritoneal cavity. Recovered promptly from the operation. On Nov. 15 developed nervous symptoms, with irritability, and nodding of head when disturbed. Was held by the other monkeys as though ill. The nervous symptoms gradually disappeared, but the monkey became weaker — refused to eat. Chloroformed Nov. 9. Autopsy showed an old tuberculous lesion of the lung with a generalized tuberculosis throughout the abdominal organs.

CASE No. 7. E. H. W., age eight, male (American born of Scotch parents), living in Middleboro, Mass. Sanitary condition of dwelling good. No other case in the family at this time. Patient well developed and nourished.

Acute attack Sept. 17, 1910, preceded by vomiting, accompanied by fever (102° F.), frontal headache, pain and tenderness on left side, also right shoulder and arm, coryza, cough, constipation. Paralysis appeared five days later involving the left leg. Slight difficulty in voiding urine.

On Nov. 13, when the specimen was obtained for inoculation, patient was but slightly ataxic in his gait, paralysis was disappearing and general condition was distinctly on the mend.

*Monkey* (*7*). On Nov. 13, 1910, 4 ccm. were injected into right brain, 4 ccm. into left brain, 75 ccm. into peritoneal cavity. Recovered well from the operation and soon began to climb and jump. Nov. 15 exhibited trembling or shivering motions. Otherwise negative. Dismissed from observation Feb. 2, 1911.

CASE No. 8. K. J. W., age ten years, male (American born of Scotch parents), living in Middleboro, Mass. Older brother to the preceding case. Sanitary condition of dwelling good. In intimate contact with his brother during the course of his acute illness. Felt well, however, up to the day of acute attack, which occurred Nov. 3, 1910, with high fever accompanied by pain and tenderness in back of neck, lasting forty-eight hours. There were also gastro-enteritis and vomiting.

Paralysis of right leg was noticed on fourth day.

On Nov. 13, when specimen was obtained for inoculation, leg was still paralyzed, the tonsils were injected and there were coryza and cough.

*Monkey* (*8*). On Nov. 13, 1910, 4 ccm. were injected into right brain, 4 ccm. into left brain and 50 ccm. into peritoneal cavity. Recovered promptly from the operation, and nothing abnormal was noted subsequently. Dismissed from observation Feb. 2, 1911.

CASE No. 9. A. T. McE., age six years, female (American born of Irish parents), living in North Easton, Mass. Sanitary condition of dwelling fair. No other case in family. Onset Nov. 21, 1910, with coryza, fever, pain and tenderness in abdominal region. Paralysis of both legs appeared three days later.

On Nov. 25, when specimen was obtained for inoculation, patellar reflexes were absent. Patient was unable to walk. Hyperesthesia and pain along spine were decreasing. Throat injected, tonsils swollen.

Gave history of having passed two round worms a few weeks before the acute onset.

*Monkey* (*9*). On Nov. 25, 1910, 4 ccm. were injected into right brain, 4 ccm. into left brain, 70 ccm. into peritoneal cavity. Recovered promptly from the operation. On Dec. 1 had a suspicious way of lifting the left forearm and wrist. This, however, soon passed away. Dismissed from observation Feb. 2, 1911.

CASE No. 10. Dr. R. (age about thirty-five), American, living and practicing in Springfield, Mass. Sanitary condition of dwelling excellent.

Specimen was taken from his nose and throat on Dec. 5, 1910, for the reason that he had seen and been associated with several cases of infantile paralysis. The object was to determine whether or not such persons could possibly act as carriers.

At the time of taking this specimen the doctor was in good health, but had a slight coryza.

*Monkey* (*10*). On Dec. 5, 1910, 2 ccm. were injected into right brain, 4 ccm. into left brain, 65 ccm. into peritoneal cavity. Recovered well from the operation, but on second day trembled as though shivering from the cold. This symptom soon passed away, however. In a few days temperament seemed somewhat altered, was less wild, but no other suspicious symptoms developed. Dismissed from observation Feb. 1, 1911.

CASE No. 11. H. R., age three years, female, well developed and nourished, living in Springfield, Mass. Sanitary condition of dwelling excellent. Living at home with her father, a practicing and school physician.

A younger sister, age nine months, had an attack of poliomyelitis on July 15, 1910, resulting in a complete right hemiplegia.

Acute attack Nov. 23, 1910, with gastro-enteritis, vomiting, fever and pain in her left face. The next day paralysis of the left face was noticed.

On Dec. 5, when the specimen for inoculation was secured, paralysis of the left face persisted, throat was injected, and tonsils were enlarged. Otherwise, general condition of health good.

*Monkey* (*11*). On Dec. 5, 1910, 4 ccm. were injected into right brain, 4 ccm. into left brain, 60 ccm. into peritoneal cavity. On Dec. 6, seemed to be lame in right leg and had a tendency to fall to the right side. Pupils equal and reacted to light. Did not exhibit usual fear and refused to eat. On Dec. 7, seemed delirious and moved continually in circles to the right. The condition gradually improved so that by Dec. 14, the monkey climbed and jumped much as usual, but still exhibited lameness of right arm.

Chloroformed Dec. 21 and near the right motor area was found a blood clot which accounted for the paralysis.

CASE No. 12. M. B., age twenty-one, female, American, living in Springfield, Mass. Sanitary condition of dwelling good. No other case in family. Library assistant, well developed and nourished.

Acute attack Dec. 4, 1910. Slight rise of temperature, marked change of temperament, pain and tenderness in the neck, paralysis of right face and neck. For three or four weeks before onset, constipation, which still persists.

On Dec. 8 when specimen was obtained for inoculation, paralysis of right face was still present. Throat injected, tonsils hypertrophied, adenoids present, lower turbinates swollen, injected and bleed easily.

*Monkey* (*12*). On Dec. 8, 1910, 4 ccm. were injected into right brain, 4 ccm. into left brain, 60 ccm. into peritoneal cavity. Recovered promptly from the anesthetic and never showed suspicious symptoms.

Dismissed from observation Feb. 2, 1911.

CASE No. 13. S. S., age two years three months, male, Hebrew, living in Chelsea, Mass. Sanitary condition of dwelling fair.

Acute attack Dec. 10, 1910, with fever, coryza, bronchial cough, pain and tenderness in right knee. Paralysis appeared on the same day involving the right leg.

Child well developed and nourished.

On Dec. 15, when specimen was obtained for inoculation, paralysis had disappeared.

*Monkey* (*13*). On Dec. 15, 1910, 4 ccm. were injected

* Suspected carrier.

into right brain, 4 ccm. into left brain, 20 ccm. into peritoneal cavity. (In disconnecting the filter, the cotton plug was sucked in and for fear of contamination this material was again passed through a Berkfeld filter.) Recovered promptly from the anesthesia and never showed suspicious symptoms.

Dismissed from observation Feb. 2, 1911.

CASE No. 14. A. B., age twelve months, female, French-Canadian, living in Lawrence, Mass. Sanitary condition of dwelling poor.

Acute attack Dec. 8, 1910, with fever and sore throat. Three weeks previous, the child had spells of vomiting lasting for two days and was generally peevish, then seemed to be in good health up to date of onset. Paralysis involving the left arm appeared on Dec. 9.

On Dec. 15, when specimen was secured, child was in fair health except for the paralysis. She was constipated, however, and throat was sore and injected, tonsils were enlarged and reddened, and there was some cough.

*Monkey* (*14*). On Dec. 16, 1910, 4 ccm. were injected into right brain, 4 ccm. into left brain, 20 ccm. into peritoneal cavity. Recovered slowly but completely from the operation and never showed suspicious symptoms. Dismissed from observation Feb. 2, 1911.

CASE No. 15. M. F. B., age nine months, female (American born, French-Canadian parents), living in Wakefield, Mass. Sanitary condition of dwelling fair. No other case in family. A well developed and nourished child. Breast fed until one month before onset, when she was partially weaned and given cow's milk and baked potatoes.

Acute attack, Dec. 15, 1910, with fever, brain symptoms, vomiting, convulsions, pain and tenderness. Paralysis of right leg, right arm and right face appeared two days later.

On Dec. 18, when specimen was secured, the child was unconscious. She died on Dec. 20. Autopsy refused.

*Monkey* (*15*). On Dec. 19, 1910, 4 ccm. were injected into right brain, 4 ccm. into left brain, 50 ccm. into peritoneal cavity. Recovered promptly from the operation and never showed suspicious symptoms.

Dismissed from observation Feb. 2, 1911.

CASE No. 16. T. G., age twenty-three years, male, Italian, living in Southbridge, Mass. Sanitary condition of dwelling fair. Patient well developed but poorly nourished.

Acute attack Dec. 27, 1910, with fever, pain and tenderness on the right, a week later extending to the left side, along the spine and the extremities, profuse sweating and evidences of vasomotor change of lower extremities.

Paralysis appeared at time of onset and involved at first only the thumb and index finger of the right hand. The next day paralysis invaded the right forearm and arm, thence extending to the right leg, where it was complete. It lasted only two days, however, during which period no reflexes could be obtained.

Jan. 10, when the specimen was secured, all the reflexes were exaggerated on the right, and diminished on the left side. There was no rise of temperature. Tongue clean, tonsils enlarged, soft palate and uvula congested and slightly edematous, noticeable change of temperament.

*Monkey* (*16*). On Jan. 10, 1911, 3 ccm. were injected into right brain, 4 ccm. into left brain, 30 ccm. into peritoneal cavity. Recovered slowly from the anesthesia and never showed suspicious symptoms.

Dismissed from observation February, 1911.

CASE No. 17. G. S., age seven years, female, American, living in Ware, Mass. Sanitary condition of dwelling excellent. No other case in the family. Attended public school and there occupied a seat immediately behind a boy who, just previous to her attack, was out of school with poliomyelitis.

Onset Dec. 11, 1910. No fever. Paralysis appeared the same day involving both legs. Pain and tenderness, more pronounced in the thighs, were a marked feature. Hiccough frequent and persistent since attack. For a week or ten days before her attack the mother remarked a peculiar change of temperament.

On Jan. 12, 1911, when specimen was secured, she was completely recovered, throat normal, tonsils slightly hypertrophied, otherwise a normal child.

*Monkey* (*17*). On Jan. 13, 1911, 4 ccm. were injected into right brain, 4 ccm. into left brain, 30 ccm. into peritoneal cavity. Recovered promptly from the operation and never showed suspicious symptoms.

Dismissed from observation February, 1911.

CASE No. 18. W. C., age nineteen months, male, French-American, living in Ware, Mass. Sanitary condition of dwelling fair. No known history of contact with any other case.

Acute attack on Jan. 1, 1911, with vomiting, accompanied with convulsions and diarrhea, fever, stupor, retraction of head, rigidity of right arm and right leg. Paralysis followed eight days later involving right arm and right leg.

On Jan. 12, when specimen was secured, the baby was moribund, reflexes were absent on both sides though the child could move its legs and arm. Nystagmus, tongue heavily coated, throat injected, tonsils hypertrophied. Died on Jan. 18, 1911. Autopsy refused.

*Monkey* (*18*). On Jan. 13, 1911, injected 4 ccm. into right brain, 4 ccm. into left brain, 10 ccm. into peritoneal cavity. Recovered promptly from the anesthesia and never showed suspicious symptoms. Dismissed from observation February, 1911.

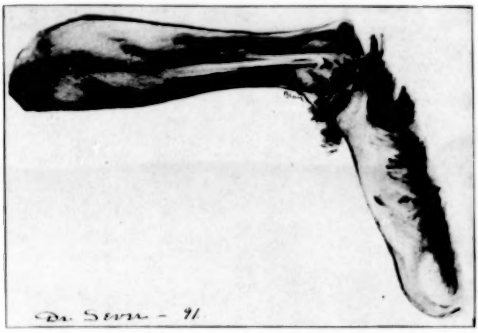
### SUMMARY AND CONCLUSIONS.

The fact that the virus of epidemic poliomyelitis was not demonstrated in the buccal and nasal and pharyngeal secretions of these eighteen cases is not proof that it may not have been there. In any event, the virus would have been greatly diluted, owing to the relative large amount of salt solution used to wash the mucous membrane. Furthermore, under the conditions of the experiment, the virus may have been so attenuated as to be incapable of infecting monkeys.

It is well known that a considerable quantity of the virus from the central nervous system of man is sometimes required to initiate the the infection in monkeys.

Our results must not be construed as in any sense as disproving the assumption that the infection in this disease may be discharged from the mucosa of the upper respiratory passage and enter through the same channel.

## AN EXPERIMENTAL STUDY OF TENDON REGENERATION.*



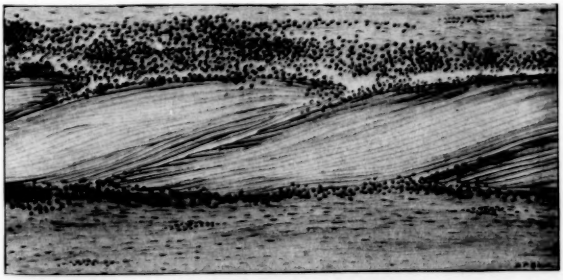
BY JAMES WARREN SEVER, M.D.,

*Junior Assistant Surgeon to the Children's Hospital, Boston; Member of the American Orthopedic Association.*

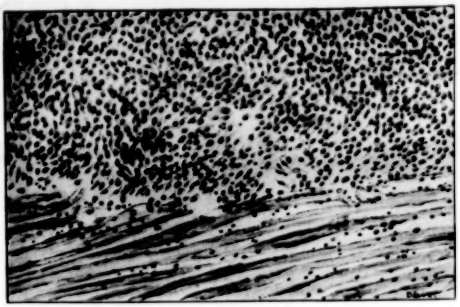
(From the Laboratory of Surgical Pathology, Harvard Medical School.)

SEVERAL years ago Dr. J. A. O'Reilly, of St. Louis, and Dr. D. P. Penhallow, of Boston, conceived the idea of studying the effects of tendon

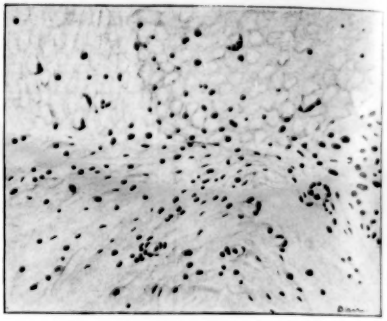
* This work was aided in publication by a grant from the Proctor Fund for the Study of Chronic Diseases in the Harvard Medical School.



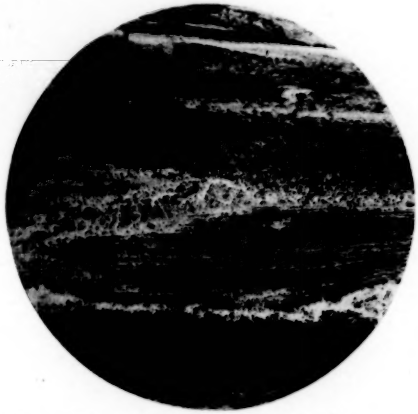
EXPERIMENT No. 3. DRAWING No. 1. Drawing of gross specimen. Skin not adherent to underlying tissues. Note complete regeneration along line of Pagenstecher of a new "tendon" apparently as large as normal. This "tendon" functionated perfectly. Compare drawings A and B.



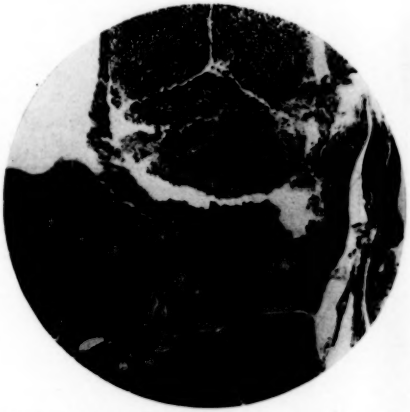
EXPERIMENT No. 3. No. 1. DRAWING A. Shows normal leg of same cat.



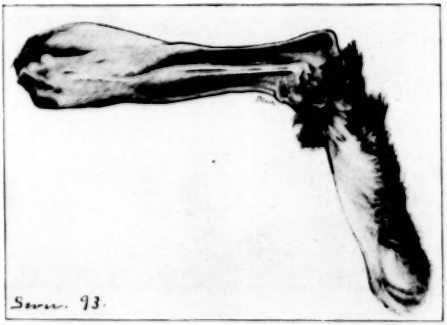
DRAWING B. Shows regenerated "tendon" about line of Pagenstecher. Note adhesions below "tendon," also slight sag to the new "tendon." Note also that the newly regenerated "tendon" is nearly as large as the normal one.



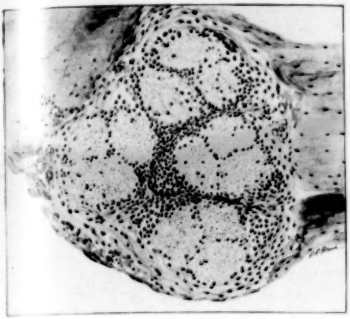
EXPERIMENT No. 3. DRAWING No. 2. Low power. Shows a longitudinal section of the regenerated tissue. It also shows the twisted Pagenstecher strands in the middle, with the proliferation at its outer edges, partially invading the Pagenstecher. The proliferation comes from the tendon sheath and probably from the peritendineum, and is composed of dense fibrous tissue externally and of endothelial leucocytes adjacent to the Pagenstecher.



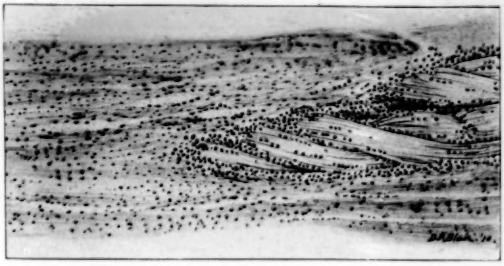
EXPERIMENT No. 3. DRAWING No. 3. Shows high power of edge of preceding longitudinal section. Note marked reaction of the peritendineum and infiltration of Pagenstecher with endothelial leucocytes and fibroblasts. Time, five and one-half months.
A, Pagenstecher.
B, Fibroblasts and endothelial leucocytes.



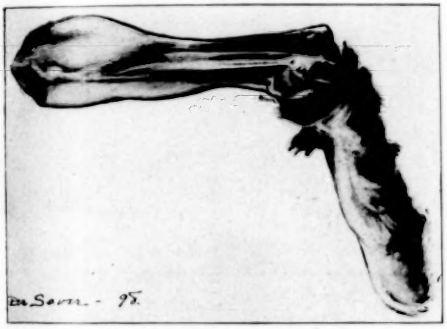
EXPERIMENT No. 3. DRAWING No. 4. Shows a drawing of high power cross section of preceding longitudinal section (see Experiment 3, No. 2). Shows two strands of the twisted Pagenstecher thread with but little infiltration of the Pagenstecher by fibroblasts. Time, five and one-half months.



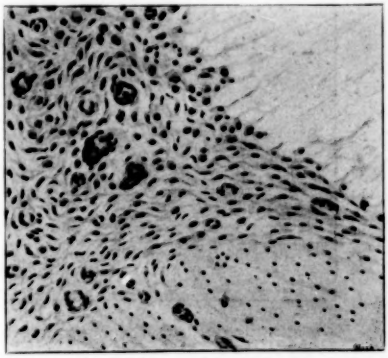
EXPERIMENT No. 3. DRAWING No. 5. Shows a micro-photograph, low power, of longitudinal section corresponding to Drawing No. 2. Shows some infiltration of the strands of thread with fibroblasts and the new fibrous tissue about the thread.



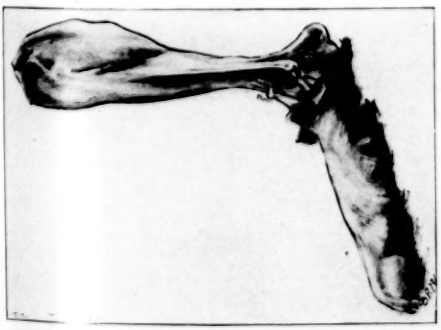
EXPERIMENT No. 3. DRAWING No. 6. Micro-photograph, low power cross section. Shows Pagenstecher thread with infiltration with fibroblasts from the tendon sheath. Time, five and one-half months.



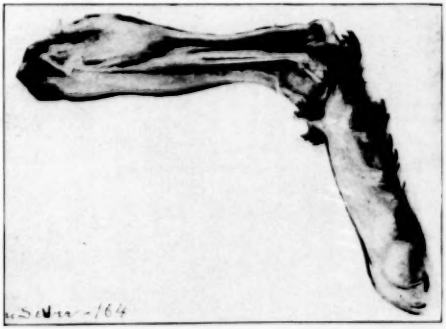
EXPERIMENT No. 4. DRAWING No. 7. See text for detail of procedure. Represents side view of regenerated process. Time, three and one-half months.



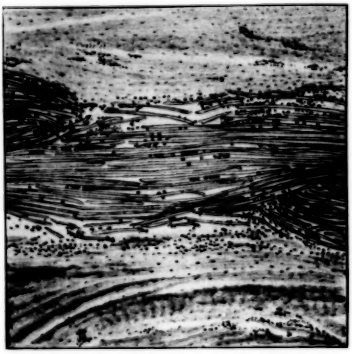
EXPERIMENT No. 4. DRAWING No. 8. Lower-power cross section of Drawing No. 7. Shows silk strands with infiltration of fibroblasts from new formed connective tissue about the silk, more marked than usual. Time, three and one-half months.



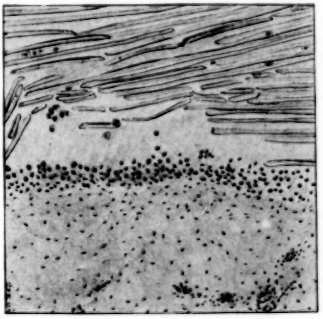
EXPERIMENT No. 4. DRAWING No. 9. Low power longitudinal section of No. 7. Shows infiltration of silk, with fibroblasts from new formed connective tissue about the silk.



EXPERIMENT No. 5. DRAWING No. 10. Shows gross lateral view of regenerative process between the belly of the gastrocnemius and the os calcis. Time, three and one-half months.



EXPERIMENT No. 5. DRAWING No. 11. A high power cross section of Drawing No. 10. Shows the edges of the silk, with marked proliferative reaction about the silk. Very little infiltration of silk. Also note giant cells. Time, three and one-half months.



EXPERIMENT No. 6. DRAWING No. 12. Shows result at end of two months, following resection of tendo achillis. Note gap between belly of gastrocnemius and os calcis. There was no regeneration of the tendo achillis. Sections showed nothing of importance. In this case nothing was used to bridge the gap in the resected tendon. The sheath was left flat and open. This shows the importance of the presence of the sheath and peritendineum in regenerative processes. For in this case there was no regeneration of the tendo achillis.

EXPERIMENT No. 7. DRAWING No. 13. Tendo achillis excised for 1¼ in. Tendon sheath *closed*. Skin sewed with continuous Pagensteecher. Cat killed at end of two months. Sections showed normal tendon regeneration. Nothing was inserted in this case to take the place of the resected tendon, but the sheath was closed. For contrast see Drawing No. 12. Note spindle shape of tendon similar to bone callus.

SECTION, low power, No. 14. Shows a low power drawing of a piece of silk thread surrounded by apparently normal tendon. The silk, it should be noted, is not greatly infiltrated by the tissue, although there are a few cells among the fibers, presumably old ones, left from the original inflammatory reaction at the time of insertion. The tissue about the silk is the fascia lata, and the condition is very similar to the one shown by Lange's sections, where the site of the operation was practically the same. The silk was slightly adherent to the surrounding tissue. This silk had been *in situ* about two and a half years, showing that there is very little probability of its becoming absorbed.

No. 15. Shows an edge, under high power, of the low power section shown in No. 14. Note the freedom from either cellular or fibrous infiltration of the silk. Note also that the silk fibers show plainly, and that there has been no tendency towards absorption. The layers of cells along the edge of the silk are probably endothelial leucocytes, the remains of the original proliferative process. The wavy elastic fibrous tissue seen outside of the cells is apparently normal tendon, making a thick tendinous band about the silk. The silk was adherent to this tissue in the gross specimen, but histologically shows very little infiltration.

regeneration by means of animal experimentation, and asked me to assist them in the work. From 1907 to 1909, we have done thirteen operations together on cats. The technical work has been carried out by the Laboratory of Surgical Pathology, and the study of the specimens, the supervision of the drawings, the collection of the data and the study of the literature has fallen to me. Since the operations ceased in 1909, the direction of the work has been entirely in my hands, as has been the final preparation of the paper. I am greatly indebted to Drs. O'Reilly and Penhallow for their early assistance and regret that they were not able to carry this work along to its completion.

This tendon regeneration was to be studied by resecting the tendon and inserting some foreign body, such as silk, linen thread or catgut, about which the tendon might regenerate. It was also planned to note the effect upon regeneration of the tendon, the presence of or removal of the tendon sheath, both with and without the presence of silk or linen threads.

A preliminary report of our work was made by me, after we had been experimenting a little over a year, at the October meeting of the Boston Orthopedic Club, in 1908. At this time some of the gross specimens were shown and the work outlined; since then it has been carried further, and I am now prepared to offer some definite results and conclusions. Before taking up the experiments in detail, it will be of interest to review briefly the literature which has a bearing on the subject.

The older and, in fact, the first method of tendon transplantation was that devised by Nicoladoni in 1880, who sutured the healthy or functioning tendon to the paralyzed or non-functioning tendon. This method proved inefficient on account of the liability of the distal end of the tendon to stretch. The periosteal insertion was originated by Drobnik, and was enlarged upon and applied clinically by Lange.

To obviate this difficulty, Lange first applied the periosteal insertion to clinical cases. By periosteal insertion is meant the method by which the transplanted tendon or healthy tendon is sutured to the point of insertion of the paralyzed tendon, by stripping off the periosteum at that point or at a point nearby. By this method one is able to choose, not only the point of insertion which will give the greatest mechanical efficiency, but also one secures a more permanent and stronger attachment. He showed anatomically that his device was successful by an examination of the tissues a long time after the operation.

Lange, in 1902, reported the findings in one case of a man, two and a half years after operation, where the quadriceps tendon had been lengthened by silk strands, which were inserted into the tibia. He stated that he found a "tendon" as thick as a lead pencil running in the subcutaneous fatty tissue, surrounded by a layer of loose movable connective tissue. There was no true "tendon" sheath present. The newly formed "tendon" was a tough, bluish, round string, about the color of the joint capsule. The silk threads were not destroyed, but had become infiltrated by the new growth.

Lange stated that microscopic examination showed in the central portion of the new "tendon," closely applied to the silk threads, a layer of tissue apparently identical with that of normal tendon, i. e., connective tissue fibers, were arranged parallel to each other, while elastic fibers and blood vessels were almost wholly absent. In the peripheral portion of the "tendon" there were cells and fibers like those of true tendon, but, in addition, blood vessels and fat cells were found here and there. The silk fibers, 12 cm. long, lay in a mass consisting of tendinous tissue, whose wall was from 2 mm. to 3 mm. thick, and whose lower end ran into the periosteum of the tibia.

This finding was of great interest, but his histological description was not sufficiently accurate to settle whether or not the new tissue forming along such silk strands is true tendinous tissue or is merely fibrous connective tissue taking up the function of tendon. It is probable that no true tendon sheath is regenerated around one of these tendons formed where it has been destroyed or where no sheath originally existed.

The experimental work described in this paper was undertaken, of course, with a knowledge and appreciation of Lange's work on the lengthening of tendons by means of silk, and with the idea of obtaining, if possible, a definite pathology and histology following such a procedure; believing that the definite knowledge so obtained would be of great benefit to orthopedic surgery, especially in its application to the increasing number of cases of anterior poliomyelitis.

Besides Lange, Borst, Seggle, Rydygier and Vulpius have done animal experiments on the use of silk in tendon suture, and Vulpius and Lange, from secondary operations, have been able to see the gross results of their primary efforts.

An attempt was made to create a new tendon sheath by Ritter, who in 1908, working in Payer's clinic in Greifswald, used veins taken from animals. He enclosed a stump of the tendon in the ends of the vein and so formed a new artificial sheath along which the new tendon could grow. In Lange's case, however, a condition was found in which only connective tissue regeneration took place, which lead to the formation of a kind of a tendon mass through and along which the silk slides as a working tendon.

Seggle, who has done some interesting research work on tendon regeneration, states that the new tendon is developed after tenotomies by a process of organization of the blood which is poured out from the cut sheath and divided tendon.

Following tenotomies the healing process is as follows: According to Seggle, on the tenth day the inner layers of the tendon sheath consist of long slender spindle cells, with marked fibrillations. By the thirteenth day the regenerative process is already far advanced. By the thirty-eighth day the regeneration extends to the whole

cross section, and by the fiftieth day the climax of the regenerative process has been reached.

Mencière, in 1906, working in an experimental research on the creation of artificial tendons and its application to the human being, used silk thread, folded on itself like a skein, and attached by single threads of this skein at each end to the ends of the resected tendon. He obtained a normally functioning muscle attached to the new muscle in about two months after the operation. Six months after the operation he killed the animal he used for the experiment, and in examining the new tendon found that it was much larger than a large lead pencil and very much larger than the corresponding normal tendon Achilles of the opposite leg. In gross appearance it was normal, i. e., looked like tendinous tissue, and there were no adhesions to the surrounding tissue, "but there was no tendon sheath present."

He stated that the silk thread had become "penetrated, absorbed and replaced by a formation of fibrous tissue, and in place of an artificial tendon of silk there was found a living tendon of fibrous tissue." His statement that the silk is absorbed, of course, does not seem possible in view of the findings of all other investigators, for it is well known that silk is not absorbed by any tissue, but may become thoroughly permeated by new fibrous or tendinous tissue to such an extent that it is well hidden. Mencière had made no microscopic sections, and, if he had, unquestionably would have found the silk imbedded in the new growth.

Anzilotti (Pisa) reported at the Italian Surgical Society in September, 1906, the results of some of his experiments. He found that the sheath played an important part in the integrity and regeneration following tenotomies.

Vulpius uses silk at times for lengthening tendons, but does not think it should be considered a normal proceeding. He does not think that a foreign body such as silk should be introduced except in cases of absolute necessity. In only rare cases is an artificial tendon absolutely indispensable.

Froelich believes that the use of an artificial tendon gives no satisfaction. He believes that they become infected, either immediately or late, and often cut through the skin on account of muscular contractions. It is the exception when they are successful, and that they form an unusual experience without any practical value.

Alexandro Guaccero, in a communication before the Italian Orthopedic Association at Rome in October, 1908, described a number of experiments which he did on rabbits with a view to showing the normal processes of repair at different stages following tenotomies. In some cases he also inserted silk to take the place of the resected tendon. He stated that in some cases after ninety days the silk was "absorbed." Also that when the sheath was removed, the regeneration was fibrous and along the line of the silk. This finding in regard to the absorption of silk is, of course, erroneous. A careful preparation of his microscopic sections, combined with an intelligent study of them, unquestionably would have shown the silk present.

Muller, in Philadelphia (1906), reported the result of some observations on dogs in which he replaced the tendon by a silk cord and found that the tendon was replaced by a fibrous band, which allowed good function.

These are the opinions of those who have used this procedure early, that is, before the technic was perfected, and before experience had shown the method to be of great value, and of general use in many cases.

The details of normal tendon repair I will cite briefly so that the reader may be familiar with the process. (I am indebted to Dr. F. L. Richardson, of the Laboratory of Surgical Pathology, Harvard Medical School, for this abstract from an unpublished paper by him on tendon suture.)

"The process of repair of a tendon that is simply cut without breaking the continuity of the tendon sheath is as follows: Hemorrhage into the interval between the ends of the cut tendon, which is followed in due time by an inflammatory exudate. This exudate infiltrates the surrounding tissue, including the tendon, for a considerable distance about the wound. This exudate, which consists of leucocytes, serum and fibrin, organizes, that is, it is replaced by granulation tissue which arises by proliferation of the cells of the peritendineum, the septa and the inner layer of the tendon sheath, and practically not at all from the inner part of the tendon. The granulation tissue which arises from the peritendineum, the septa and the sheath cannot in the early stages be distinguished from the ordinary granulation tissue, which arises from any unspecialized connective tissue, but it has one important difference, namely, it tends to form a dense and but slightly elastic connective tissue, closely resembling normal tendon.

"The blood vessels which are found in this mass of granulation tissue arise in part from the blood vessels of the tendon sheath. The mass of granulation tissue thus produced is much larger than the diameter of the original tendon and forms a fusiform mass surrounding the cut ends. As the process goes on, the cells become spindle shaped and a very large amount of intercellular material is formed. The blood vessels begin to disappear early, and in small tendon they are almost wanting at the end of two weeks. With this disappearance of the blood vessels, the size of the original mass of granulation tissue diminishes."

The purpose of this work has already been called to your attention, and it only remains for me to give you a description of the experiments and the results.

### DESCRIPTION OF EXPERIMENTS.

In all there were performed by us thirteen operations on as many cats, eleven of which turned out satisfactorily, but two could not be used for our purpose, on account of the animals dying too soon after the operation for purposes of useful study.

The first cat was killed at the end of a week, the second at the end of two weeks and the third

was kept in a plaster cast for four months. Then he was allowed to run about without the cast for four weeks more before being killed, so as to permit active use of the muscles and tendons. The fourth cat was kept in a plaster cast, applied only to the leg operated upon, for four months and then killed. The fifth was killed at the end of fourteen weeks, after having had the leg in a plaster cast, but being allowed to run about, as, in fact, all the cats were while in and out of the casts. The sixth was killed at the end of eight weeks and the seventh at the end of a similar period. The last four were all killed at about three weeks after operation for purposes of control study to the work which we had previously carried out.

No. 1. Experiment 72:

Jan. 1, 1907. Tendon exposed, left fore leg, probably extensor carpii radialis. Isolated, transfixed by two sutures of chromic gut one inch apart. Tendon resected between sutures. Sutures tied loosely. No attempt made to close tendon sheath, which was opened one-half inch. Skin incision closed with chromic catgut No. 1. Plaster. Foot hyperextended.

Feb. 8, 1907. Cat killed at end of five weeks. Piece of suture tendon removed. Section showed nothing of note except hemorrhage.

No. 2. Experiment 73:

Feb. 1, 1907. Tendon extensor radialis exposed, left fore leg. Two-inch portion, about one-half inch in length, resected. Previous to resection, three strands No. 3 silk inserted, which had been dipped previously in boiling paraffine. Considerable of the paraffine coating came off during process of application. No attempt made to close tendon sheath. Skin closed with three interrupted silk sutures. Foot in plantar flexion. Plaster.

Feb. 15, 1907. Cat killed. Wound showed first intention. Sections and gross specimens showed nothing of value.

No. 3. See drawing and sections A and B (Nos. 1, 2, 3, 4, 5, 6):

Feb. 20, 1907. Cat. Ether. Incision over tendo Achilles. Tendon exposed, resected one inch, gap bridged with four strands of Pagenstecher thread. Tender sheath retained. Attempt made to close sheath with catgut. Skin closed by catgut continuous sutures. Plaster removed June 19. Leg in good condition. Allowed to use leg for a few weeks until July 11, 1907. Cat killed. Both tendo Achilles exposed for comparison. Skin not adherent to underlying tissues.

No. 4. See drawings and sections (Nos. 7, 8, 9):

Feb. 28, 1907. Cat. Ether. Resected tendo Achilles, right leg, removed piece of tendon one inch long with sheath. Six strands No. 4 black silk thread used to bridge a gap in tendon. Skin closed by catgut. Plaster bandage.

July 11, 1907. Cat killed. Skin somewhat adherent to underlying tissues at site of wound. Skin wound not apparent. Band of thickening extending from gastrocnemius muscle to os calcis and closely adherent to line of sutures. Apparently good strong "tendon" in place of resected one. Time, three and one-half months.

No. 5. See drawing and section (Nos. 10, 11):

March 7, 1907. Cat. Ether. One and one-half inch of tendo Achilles resected. Two sutures of No. 14 silver. Rubber silk used to bridge gap in tendon. Sheath not sutured. Continuous suture to skin with catgut. Leg put up in plaster at right angles.

June 19, 1907. Cat killed. Skin wound not apparent. Skin not adherent over site of wound, tendon sheath not adherent to new "tendon." Band of new tissue posterior to the silk sutures, resembling tendon. Silk apparently stretched slightly. Thickening about silk sutures making a continuous band from the gastrocnemius muscle to os calcis. Silk movable in sheath. New "tendon" strong and functionating.

No. 6. See drawing (No. 12):

May 25, 1908. Cat. Ether. Operation on left hind leg, one long incision. Tendon excised for one and one-half inches. Skin sewed up with continuous Pagenstecher. Tendon sheath not sewed but left open and flat. Leg put up in plaster at right angles. Good ether recovery.

July 28, 1908. Cat killed. See note on legend. Time, two months.

No. 7. See drawing with legend.

May 25, 1908. Same as previous, except sheath was sewed with continuous Pagenstecher.

July 28, 1908. Cat killed.

No. 8. Experiment 230:

Aug. 9, 1909. Cat. Ether. One inch of tendo Achilles removed. Sheath and peritendineum removed. Two strands of fine silk inserted through, joining the cut ends. Skin closed with continuous catgut.

Aug. 30, 1909. Cat killed.

No. 9. Experiment 231:

Aug. 9, 1909. Operative procedures same as in No. 8, except that there was no silk inserted.

Aug. 30, 1909. Cat killed.

No. 10. Experiment 232. No section.

Aug. 11, 1909. Cat. Ether. One inch of tendo Achilles resected, and two strands of fine black silk inserted. The sheath and peritendineum were removed with the tendon as far as possible, and also an extra effort was made to scrub away the peritendineum with gauze. The skin was sewed with continuous catgut.

Sept. 1, 1909. Cat killed.

These drawings and sections showed nothing of importance except the usual reparative processes, which in the gross specimens were not well marked.

A study of the gross and microscopic specimens from these experiments shows a number of very interesting facts, some of which have already been called to your attention. It is perfectly evident that although the inserted silk serves as a matrix around which dense fibrous tissue forms, it also acts as a more or less inert foreign body. Contrary to the usual belief, the silk does not become infiltrated to any great extent with the new growth surrounding it, but acts as a guide to the regenerative process, whether that process is tendinous or fibrous. Some of these sections (see Nos. 14 and 15) show silk which has been in the tissues for two and a half years without any marked signs of infiltration or absorption. The gross specimen from which these sections were made showed the silk apparently as large and strong as at the time of insertion, and quite distinct from the new tissue about it. If silk were ever absorbed, one would suppose that it would be so at the end of two and a half years. The silk in the gross specimen was adherent to the dense fibrous tissue about it and moved with it.

It should be noted that the proliferation of new "tendon" comes wholly from the peritendineum, which is the all-important structure. The im-

portance of the presence of this structure can be observed by noting the contrast between Figs. 12 and 13.

CONCLUSIONS.

(1) Silk or linen thread is an excellent material to use to lengthen tendons in suitable cases.

(2) The growth of new tissue will penetrate and permeate the silk only slightly, and in some cases not at all, and does not absorb it.

(3) When the peritendineum and tendon sheath have been removed, some foreign body such as silk is essential for regeneration, to serve as a director for the new growth.

(4) With the sheath and the peritendineum present and sutured, no foreign body need be inserted. In this case the new growth is true tendon tissue.

(5) Without the presence of the sheath and the peritendineum, no true tendon tissue can be regenerated. Such tissue is merely fibrous tissue, lacking elasticity and subject to stretching.

(6) The new "tendons" are apt to be larger and stronger than the resected ones, especially when silk has been used to replace the resected portion.

(7) Provided the sheath and peritendineum are preserved and function allowed early, adhesions may not occur. Without the sheath, adhesions may and do occur much more frequently.

*N. B.* I wish to express my thanks for the consideration shown and the invaluable assistance given in this work by Dr. E. H. Nichols, director of the Laboratory of Surgical Pathology, Harvard Medical School.

## TENDON SUTURE.

BY F. L. RICHARDSON, M.D.

(*From the Laboratory of Surgical Pathology, Harvard University Medical School.*)

THIS article is not meant to be an elaborate discussion of the special technical methods which may be employed in tendon suture, but is intended to call attention to the fundamental principles of repair of tendons which often are neglected by operators.

A tendon is a white, glistening cord, composed largely of bundles of non-elastic connective tissue which contain relatively few cells and give the tendon its strength. Surrounding the entire tendon and running between the bundles of dense connective tissue (septa), and binding them together, is a layer of loose connective tissue, the peritendineum. The cells in the bundles of dense connective tissue are highly specialized, with elongated nuclei and a large amount of intercellular material, the fibers of which run parallel. The tendon bundles are destitute of nerves. The loose connective tissue of the peritendineum and of the septa consists of cells with fibers loosely arranged. The few blood vessels and nerves of the tendon lie in these septa of loose connective tissue. The portion of this loose connective tissue which surrounds the tendon (peritendineum) is much thicker than the tissue of the septa and appears in gross as a thin, filmy sheath and, when picked up with the forceps, closely resembles the connective tissue which binds muscle bundles together. The connective tissue (septa) cannot be recognized in gross, and under the miscroscope the cells in this tissue are not numerous. The peritendineum and the septa stand in the same relation to the tendon that the periosteum and endosteum stand to bone. In fractured bone, the repair comes from the proliferation of the osteoblasts of the endosteum and of the periosteum; likewise in injuries of tendon, repair comes from proliferation of the specialized tissue of the peritendineum and of the septa.

The tendon in many places is surrounded by a definite sheath. The inner layers of the true tendon sheath are composed of connective tissue, in all respects resembling the peritendineum, with dense connective tissue outside. The tendon sheath is, however, much more vascular and contains a larger nerve supply than the tendon.

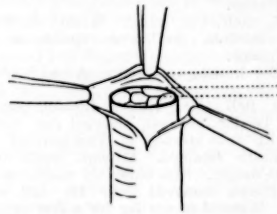

FIG. 1.

Diagram to show the relations of tendon, peritendineum and sheath.
*A*, Tendon sheath held back with forceps.
*B*, Peritendineum.
*C*, Septa.

When a tendon is cut, the ends retract, due in part to contraction of muscle and in part to elasticity of the tendon itself. The peritendineum, being less contractile, and being but loosely attached to the tendon, does not retract so much as does the denser portion and its loose meshwork falls over the cut ends of the tendon.

The process of repair of a tendon that is simply cut without breaking the continuity of the tendon sheath is:

(1) Hemorrhage into the interval between the ends of the cut tendon. This hemorrhage is followed by an inflammatory exudate. This exudate also infiltrates the surrounding tissue, including the tendon itself, for a considerable distance about the wound. (2) The exudate,

which consists of leucocytes, serum and fibrin, organizes, that is, it is replaced by granulation tissue which arises by proliferation of the cells of the peritendineum and of the septa and the inner layers of the tendon sheath and practically not at all from the denser part of the tendon. The granulation tissue which arises from the peritendineum, the septa and the tendon sheath cannot in the early stages be distinguished from ordinary granulation tissue which arises from any unspecialized connective tissue, but it has one important difference, namely, it tends to form a dense and but slightly elastic connective tissue closely resembling normal tendon. The blood vessels which are found in this mass of granulation tissue arise in part from the blood vessels of the septa and peritendineum and in part from blood vessels of the tendon sheath. (3) The mass of granulation tissue thus produced is much larger than the diameter of the original tendon and forms a fusiform mass surrounding the cut ends. As the process goes on, the cells become spindle shaped and a very large amount of intercellular material is formed. The blood vessels, also, begin to disappear early and in small tendons, like the tendons of the wrist, at the end of two weeks, they are almost wanting. With this formation of intercellular material and disappearance of blood vessels, the size of the mass of organizing granulation tissue diminishes, and because of this rapid organization, at the end of about fourteen days, in small tendons, very gentle passive motion and massage should be instituted to stretch and break up the adhesions between the tendon and the tendon sheath.

From the above process certain deductions on the operation of tendon suture can be made. It is not uncommon to see much of the peritendineum carefully dissected off, "cleaning up the tendon," apparently without realization of the fact that the greater part of the repair comes from this very tissue which is so industriously removed. The peritendineum should always be left as intact as possible. It is, however, important that any ordinary connective tissue should be carefully removed from between the ends of the tendon, if the suture is long delayed after the original injury, because this tissue proliferates and leads to the formation of ordinary scar tissue between the ends of the tendon. This ordinary scar tissue will stretch and will seriously impair the function of the tendon and form adhesions.

It is also important that the tendon sheath should be left as nearly intact as possible, and, when feasible, it should be sutured in place about the tendons. If the tube of the tendon sheath can be completely reproduced, it prevents the possibility of the ingrowth of ordinary connective

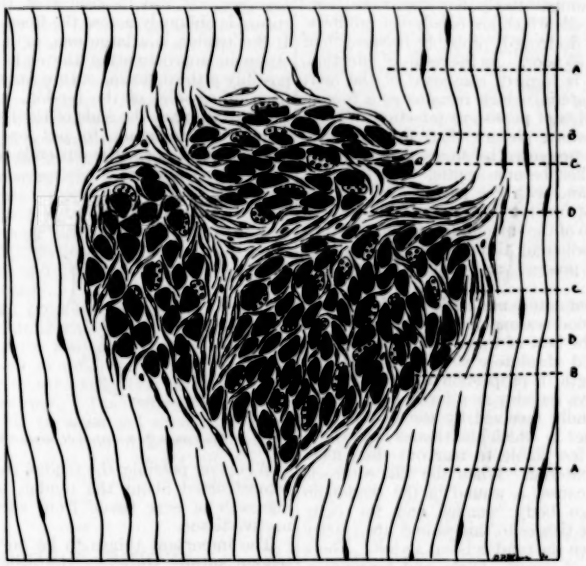

FIG. 2.
Diagram of silk suture in tendon at about the end of twenty days, to show connective tissue growing in between the silk fibers.

tissue, and to a certain extent prevents the newly formed cells of specialized connective tissue from forming diffuse adhesions that will cause trouble when attempts at motion are commenced.

The wound should be left perfectly dry because any blood that may be left behind not only retards the process of healing by leaving a greater amount of material to be organized, but it increases the amount of adhesions between tendon and tendon sheath and retards the return of perfect function.

It is hardly necessary to lay stress on performing any operation under aseptic conditions, but it is particularly important that tendon suture should be aseptic because a large part of the tendon, i. e., the intercellular fibrils, has little or no vitality. If bacteria infect a wound of the tendon, the comparatively few specialized connective tissue cells which are capable of proliferation are easily destroyed, probably because their blood supply is so poor. As the result of infection, a large slough is formed, composed of the inert intercellular material which remains as a foreign body and a nidus of persistent infection. There is no more forlorn picture than the resistant, sloughing mass presented by an accidental tendon wound which has become septic, with the long convalescence and with the partial and possibly complete loss of function, not only of the sutured tendon, but also of the surrounding tendons, which have become adherent through extension of the inflammatory process and the long-enforced immobility.

Many different suture materials have been used, but there are good reasons to believe that twisted silk is by far the best of them. It can be boiled and so rendered absolutely sterile. It has considerable strength in proportion to its size. Although it always remains as a foreign body, it is flexible and kindly received by the tissues, and from the manner in which the tissues heal about it, it is much less liable to tear out than most other suture material. When the silk suture is introduced, it causes a wound in the tendon in which a foreign body remains and the early reactions of the tissues to this wound are exactly the same as when the tendon is cut across. There is an exudate of serum, fibrin and leucocytes, with a little blood, which goes in between the individual fibers of the silk. This exudate is replaced by granulation tissue of the specialized type which arises from the peritendineum and septa, and there are numerous giant cells which form about the silk fibers. The granulation tissue is early converted into specialized connective tissue, like the tissue that forms between the cut ends of a tendon, and since this tissue runs everywhere between the fibers of the silk thread, it virtually splices the silk into the tendon as one rope is spliced into another, instead of incasing it as happens with some other suture materials.

Because the fibers of the tendon are arranged parallel, with their axes in the same line as the pull of the tendon, and because the material binding the bundles together is very loose, sutures are very likely to pull out unless some special method of placing them is used which will make the pull across the fibers of the tendon instead of parallel to them. There are numerous ways of placing these sutures, one of the best of which is shown in the illustration. The first stitch is introduced in the shorter end of the tendon about a quarter of an inch from the cut end. (1) The suture is passed through the tendon transversely and (2) then back parallel to the first stitch at about the same distance from the cut end, but a little to one side of the first stitch. A half knot is tied, not too tight. (3) The same suture is then passed through the other end of the cut tendon, and while the assistant holds the cut ends together, the suture is (4) passed back parallel to the third stitch, a half knot is tied and the two free ends of the suture are securely tied together. It will be seen that the pull of this suture is obliquely across the fibers of the tendon. If the tendon is a large one, or if there is much strain in approximating the ends, a second and possibly a third similar suture may be introduced from other sides of the tendon. As this suture tends to displace the ends of the tendon laterally, it may be necessary to put one through-and-through suture near the cut ends to hold them in close approximation.

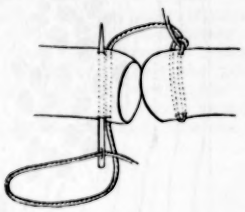

FIG. 3.
Diagram to show method of suturing described.

Wherever possible, the tendon sheath should be reconstructed about the tendon to prevent the ingrowth of scar tissue from surrounding connective tissue.

The important things to be borne in mind in tendon suture, stated in the order of their importance, are:

(1) Asepsis. (2) Preservation of peritendineum. (3) Approximation of ends. (4) Restoration of tendon sheath. (5) Dryness of wound.

## Clinical Department.

### NOTE ON A CASE OF PARALYSIS AGITANS AND CEREBRAL ARTERIOSCLEROSIS.

BY WM. PEARCE COUES, M.D., BOSTON.

A NUMBER of points about this case seem worthy of a brief report. The patient was a gentleman of seventy-three, married, of superb physique and previous good health, but for occasional attacks of lumbago and a question of gallstones some years ago. His habits were excellent; his life had been a very strenuous one. For three years past there

was noticed slight though increasing mental impairment. Tremor of the hands was first noticed about seven months previously. The attacks to be described would come on quite suddenly, there seemed to be an almost perfect cycle in the different manifestations. The blood pressure was 210, 200 and 160 at various times. There was a faint trace of albumen in the urine at different times. The heart and lungs were not abnormal. The attacks were ushered in by great mental irritability preceded by sleeplessness. Delirium would follow, violent and constant. Restraint was absolutely necessary at this tine. Quite suddenly a period of complete unconsciousness with relaxed sphincters would supervene, lasting for hours. Accompanying this part of the attack were transient paralyses. At this time the respiration was as low as three or four to the minute at repeated intervals. At different times there was absolutely no respiration for three quarters of a minute; then one or two breaths would be taken, and the process gone over again. Many times it appeared as if death were a question of minutes, but the pulse was never completely lost. The attacks lasted over a period between three and four weeks. For two days respirations were between four and ten to the minute repeatedly. From 4 A.M. Aug. 6 to 10 A.M. Aug. 8 the respirations were recorded in the nurse's book thirty-five times; the lowest was 3; the highest, 8 to the minute. Aug. 8 they arose to 16 and from this time improvement was slow but steady.

Hyoscine, the bromides, iodide of potassium, codeine and hydrotherapy had not the slightest effect on the intense restlessness and wild delirum which threatened to wear the patient out. Today, about six months after this period, the patient feels very well. The mind is absolutely clear; he is able to walk and drive and enjoy life. He writes well, though with some difficulty. The characteristic gait and tremor are all the symptoms left. There has been no return of the respiratory embarrassment.

## Reports of Societies.

### AMERICAN GASTRO-ENTEROLOGICAL ASSOCIATION.

FOURTEENTH ANNUAL MEETING, HELD AT THE BELLEVUE-STRAFFORD HOTEL, PHILADELPHIA, PA., WEDNESDAY AND THURSDAY, APRIL 19 AND 20, 1911.

#### THE PRESIDENT'S ADDRESS: THE IMPORTANCE OF TONUS IN THE MECHANICAL ACTIVITIES OF THE ALIMENTARY CANAL.

DR. WALTER B. CANNON, of Boston, Mass., said that the view that tonicity of the neuromusculature of the alimentary canal is a fundamental necessity in the appearance of rhythmic movements gives an explanation of many features regarding digestion and harmonizes many diverse observations. It gives a reasonable explanation of the existence and importance of extrinsic motor nerves; it indicates the function of inhibitory nerves in the reduction or abolition of the tone; it accounts for the failure of efficient motility in atonic states of the stomach and intestines; it is in agreement with the observation that tonic contraction and rhythmic peristalsis reappear later in cases of general body-weakness; it fits admirably with the fact that the stomach of hungry animals is strongly contracted, for then the tonic state makes the organ ready for instant action on swallowing food. Indeed, I am willing to believe that the sensation of hunger results from tonic contraction of the empty stomach.

#### STRETCHING OF THE PYLORUS IN BENIGN STENOSIS.

DR. MAX EINHORN, of New York City, read this paper, which was divided into two parts. In the first he described the stretching of the pylorus in children by means of an instrument called the infantile pyloric dilating catheter. This was a flexible tube with an inflatable rubber balloon at its end. In order to introduce it beyond the pylorus, the infant must first swallow either a small duodenal bucket or a metal olive attached to a silk string. After having ascertained that this has wandered beyond the pylorus, the dilating catheter is pushed along the silk thread into the duodenum, the balloon inflated and the instrument withdrawn.

Dr. Einhorn described the cases of two infants with congenital stenosis of the pylorus in whom he had applied this treatment. One patient had entirely recovered; the other had not been benefited.

In the second part of the paper, the author considered the subject of stretching of the pylorus in the adult, and described a new instrument, called the pyloric dilator and diaphane, consisting of a pyloric dilator with a tantalum (cold) lamp at its end. The advantage of this instrument consisted in the fact that it was possible by means of it to ascertain whether the end is in the stomach or the duodenum by means of internal illumination. The author then proceeded to describe three cases of real benign stenosis of the pylorus that had been very much benefited by the treatment. In order to insure success, there must be no active ulceration in or near the pylorus; nor must the stricture be too far advanced.

DR. MORRIS GROSS, New York, did not consider it possible to get such a tube through a stenotic pylorus. He thought that if Dr. Einhorn had succeeded in getting his dilator to pass, either stenosis did not exist at all, or it was present to such a slight degree that stretching was not called for.

DR. S. J. MELTZER, New York, said that it did not sound very plausible to him that a single passage of the instrument could have been sufficient to re-establish. function. Nobody had succeeded in stretching the cardia in so short a time, yet pylorospasm was much harder to reach than cardiospasm.

DR. A. L. BENEDICT, Buffalo, admitted frankly that he could not, as a rule, get a tube down through the pylorus, and said that bile on the end of the thread was no proof that the tube had entered the duodenum. He thought that a little medication would usually overcome the condition in a case of spasm.

DR. CHARLES D. AARON, Detroit, stated that he had pulled the tube through the pylorus, whether he had dilated it or not, fourteen times in a patient, with the result that she had gained eight pounds and was still increasing in weight.

DR. JESSE S. MYER, St. Louis, said that Dr. Einhorn's experience proved that the condition called pylorospasm did exist, and that it was evident that his method was curative in a certain number of cases.

DR. WILLIAM GERRY MORGAN, Washington, D. C., cited a case in which the patient had had no symptoms on the first night after passing the dilator, probably owing to the psychic effect produced by that procedure, the pylorospasm recurring the next night. At opera-

tion it was found that no stretching would probably have been effective, owing to the nature of the cicatrix.

DR. J. C. JOHNSON, Atlanta, remarked that stenosis does not mean absolute closure. He thought that the fact that the size of the lumen can be increased by the withdrawal of instruments passed through the pylorus promised much in the treatment of these conditions.

DR. MELTZER remarked that any foreign body in the duodenum near the pylorus would normally increase the pyloric contraction.

DR. EINHORN agreed with Dr. Meltzer regarding this, but that if the resistance at first encountered was gradually lessened with the same sized bulb, one could conclude that there had been a real stricture. He considered his method applicable only to beginning strictures.

### THE OPERATIVE TREATMENT OF IMPERMEABLE CARDIOSPASM.

DR. WILLY MYER, New York, said that the cure of impermeable cardiospasm by means of dilatation is difficult or impossible. Therefore, operative measures will often be required. Von Mikulicz and Wendel attacked the cardia from the abdomen. It is said that the trouble can also be successfully and permanently cured by way of the thorax. In support of this view, I will mention a case in which a cure was obtained by means of thoracotomy, tearing the nerve filaments that enter the esophagus on each side from the pneumogastrics, and reducing the large esophageal pouch above the diaphragm with the help of a double plication.

### CARDIOSPASM IN INFANTS, WITH REPORT OF CASES.

DR. WILLIAM GERRY MORGAN, Washington, D. C., stated that reports of cases of idiopathic dilatation of the esophagus occurring in young children have appeared in medical literature from time to time, but that in a very few instances has stenosis of the cardia not due to injury been noted.

Cardiospasm with dilatation of the esophagus occurring in infants under one year of age has not thus far been reported; and it was with such cases that this paper had to deal. He had had such a case, which was treated by Dr. Einhorn's method; and had also had a case of cardiospasm in an adult which had been treated by gradual dilatation with bougies, the patient failing all the time. I stretch the cardia with Dr. Einhorn's forcible cardia dilator. This patient is now eating everything, and has gained 19 lb. in weight.

### REMARKS ON CARDIOSPASM.

DR. S. J. MELTZER, New York, referred to a case of cardiospasm published by him twenty years ago under the term "dusphagia," in which he had given the entire clinical course of cardiospasm and predicted what would be found at autopsy. The patient did not die for five years after this, and circumstances prevented him from publishing the autopsy findings. He then stated that the absence of the deglutition sound in the stomach when it is present down as far as the tenth or eleventh vertebra means an elastic stenosis.

DR. J. C. HEMMETER, Baltimore, gave an account of a very severe case of cardiospasm in which the esophagoscope went in; but in which, when the patient swallowed, there came a spasm that prevented anything from going through. He thought that a distinction should be made between this condition and those cases in which the spasm is always present. He had had only temporary success in dilating the cardia by mechanical methods.

DR. J. KAUFMANN, New York City, stated that among his patients a surprisingly large number had dated their first attack of cardiospasm to a hot day on which they had taken ice-cold soda-water. Probably the first spastic contractions led to the development of erosions, which kept up the irritation. He considered hyperacidity as another cause of erosions.

DR. L. KAST, New York, thought that the term "cardiospasm" should be dropped in favor of one suggesting the relation of the cardia with the parts of the digestive tract above and below it. He mentioned a case of reversed peristalsis of the stomach, forcing the food through the esophagus to the mouth.

DR. JESSE S. MYER, did not see why Dr. Willy Myer had not in his case tried gastrostomy with forcible stretching of the cardiospasm, and did not consider the size of the pouch a contra-indication to this procedure.

DR. JOHNSON mentioned a case of almost complete esophageal obstruction in which operation could not be considered, and described how he had managed to get a dilating instrument to pass by means of the galvanic current. The patient will probably get entirely well.

DR. ROBERT T. MORRIS, New York, stated that in cases of cardiospasm careful examinations should first be made to eliminate the possibility of irritation of the vagus at the base of the brain through eyestrain, floating kidney, adhesions in the bile-tract region, a neurotic temperament and the stigmata of decadence.

DR. EINHORN referred to absence of the swallowing sound as an aid in the diagnosis of partial cardiospasm with dilatation of the esophagus, and said that patients treated by his method get entirely well. He did not consider that there should be any difficulty in making the differential diagnosis between this and malignancy.

DR. WILLY MYER stated that his patient had been too weak for an abdominal operation, and it seemed better to adopt the thoracic route. He did not feel sure whether the double plication had really been necessary or not.

### SOME GENERAL REMARKS ON THE TREATMENT OF GASTRIC DISTURBANCES.

DR. J. KAUFMANN, New York, stated that correct treatment requires correct diagnosis, and referred to the progress made in the reading of gastric analyses, especially regarding the relationship of motor and secretory disorders, which assists in directing treatment along the right lines. Aside from properly interpreting disorders of gastric function, we have to consider their pathological meaning. There must be a differentiation of primary and secondary gastric disturbances. Among the latter, those caused by chronic appendicitis, cholelithiasis, etc., are much emphasized at present. While undoubtedly occurring, their frequency is greatly overrated, and too much importance is given to this special etiological factor, at the cost of others that are known as provokers of gastric disturbances. Every etiological factor should be taken into account. At the same time, the condition of the stomach proper requires consideration, even in cases of secondary gastric disturbances.

DR. JOHN A. LICHTY, Pittsburg, said that in spite of medical treatment carried on for a long time in cases of hyperchlorhydria, patients would often continue to oversecrete, although they might improve in general health. Quite a number of such cases, he thought, could be improved by surgical intervention. This continuance of oversecretion after the removal of the original irritant was attributed to cell-habit.

THE GASTRIC WEAK LINE IN WOUNDS OF THE ABDOMINAL WALL.

Dr. Robert T. Morris, New York City, stated that failure of union of the abdominal-wall wound after many of the stomach operations seems to call for special explanation. The failure of union apparently means a trophic disturbance, and this incidentally corresponds to the area of superficial sensory disturbance described by Head for the gastric zone. It is probable that irritation of the nerves of the stomach, referred to their respective segments of the spinal cord, is continued as an impulse to the superficial gastric area, which is commonly irritated coincidently with irritative processes of the stomach. This feature has been recorded with reference to hyperesthesia of skin zones, but the question of trophic nerve disturbance leading to failure of operative processes in the superficial gastric zone seems to have escaped attention previously.

Dr. J. C. Hemmeter said that before accepting the hypothesis of Dr. Morris, it would be necessary to prove that the stimulus went from the gastric zone to a segment of the cord from which the trophic nerve came out.

Dr. Kast considered the idea a very happy one, and said that it would again attract attention to the viscerocutaneous reflex and to the mutual reflex association between the internal organs and certain areas of the skin.

Dr. Meltzer was surprised that the idea should not have suggested itself to Dr. Morris that the stimulus might be not a nervous, but a chemical one. He thought it possible that it might be due to bile and pancreatic secretion that the stitches gave way.

Dr. A. G. Gerster, New York, said that this occurs after operations in every region of the body, and thought Dr. Meltzer's explanation quite plausible. Anesthesia alone was often sufficient to disturb the pancreatic and gastric secretions so much as profoundly to change the chemical processes of the body for a long time after the operation.

Dr. Morris stated that the fact that repair did not take place in a case in which there was irritation of the pylorus had led him to the conclusion that there was a trophic disturbance in that particular group of nerves coming from a certain definite segment of the cord.

A CASE OF BANTI'S DISEASE.

Dr. J. Fuhs, Brooklyn, said that the case of Banti's disease that he wished to present was successfully treated by splenectomy, the patient afterward passing through an attack of typhoid fever and an operation for appendicitis. He emphasized the remarkable results that followed splenectomy in this case; the lasting improvement and the ability to combat infection, and also the restoration of the blood to its normal condition as to the formed elements and to a marked increase in its coagulability.

She had a typical, characteristic attack of typhoid fever, differing in no way from such attacks in patients not operated upon, with the exception of the blood findings, which showed a rather high leucocyte count for a case of typhoid, and a relatively high polymorphonuclear leucocytosis. The reaction to the surgical interference during the course of the typhoid did not present anything characteristic, and her recovery was as rapid as could be expected in a patient not splenectomized.

Dr. Hemmeter exhibited a patient with Banti's disease showing some very peculiar landmarks. This patient had profuse hemorrhage from the bowels, ascites, a very large spleen and cirrhosis of the liver, and had been operated on for appendicitis, and had had typhoid fever. The blood-picture was typical of Banti's disease. The fact that typical splenic cells have been found by Mallory in the portal veins, Dr. Hemmeter considered striking evidence that the spleen is really the starting-point of the trouble, and not the liver.

Dr. Kaufmann referred to a case of his in which some clinical facts pointed to the origin of the disease in the spleen, and said that this organ should be removed when one can be sure that it is the primary seat of the trouble. He did not consider the blood-picture typical, it having been that of pernicious anemia in his case.

Dr. J. C. Bloodgood, Baltimore, said that in three cases of Banti's disease in which splenectomy was not done the results had been just as good as in three in which it was done. The treatment was rest with arsenic and iron.

Dr. L. Kast believed Banti's disease to be only a symptom-complex, and stated that the fact that it might be a syphilitic or a post-syphilitic condition should be borne in mind.

Dr. Fuhs stated that clinically it was impossible to differentiate between cases of Banti's disease and cases in which tuberculosis or granulomata of the spleen were found. He thought that the hemorrhage and the blood-findings spoke in favor of its being a toxemia. The Wasserman reaction had been positive in two recently published cases.

THE RELATION OF SYMPTOMS TO PATHOLOGICAL FINDINGS IN CANCER AND ULCER OF THE STOMACH.

Dr. J. C. Bloodgood, Baltimore, spoke of a case of ptosis of the stomach and colon, the first case that he had resected for ptosis. Medical treatment did not decrease the residuum in the stomach, which amounted to 200 ccm. He resected a little beyond the pylorus to a point that would make a straight line of the greater curvature and of the duodenum, suturing the duodenum to the stomach according to the method of Kocher, and then turning in the end. Dr. Bloodgood considers resection of the stomach for ptosis the simplest resection, because there are no adhesions. Things are so relaxed that there is very little shock. This patient had no post-operative complications after thirty-six hours. He has been relieved of the stasis of material in his stomach and colon, causing constipation; and the diarrhea is also over. The operation has been done ten weeks, and the man has gone back to his work.

The other case was one in which he suspected cancer of the pancreas. On exploring the abdomen, he found a small nodule on the head of the pancreas. There was a large gall bladder; and in the common duct he could feel this nodule. It was not a stone. Dr. Bloodgood considered it impossible to imagine a cancer of the diverticulum of Vater that would not infiltrate the duodenum. Local resections of the tumor itself have been done without any success, owing to the fact that the cancer has been cut through. In this case, in which there were clay-colored stools before operation, bile appeared with the first stool; and the patient is gaining in weight, showing that the loss of the pancreatic secretion is not incompatible with a gain in weight.

Dr. Kaufmann said that if the operation in the first case was performed merely on account of the location and size of the stomach, he did not believe that these were sufficient indications for any operative procedure. Tonus he considered very important in cases of a neurasthenic type. Stagnation might occur periodically, and disappear again; but this condition did not require operation.

DR. EINHORN'S opinion had always been that gastroptosis as such was not at all important, and that retention was almost never associated with it when it existed without any other condition at the pylorus.

DR. HEMMETER called attention to the fact that Dr. Matthews, of Chicago, had shown that removal of the duodenum was almost as fatal as removal of both kidneys.

DR. BENEDICT said that the word "ptosis" should be limited to mean a dropping down of an entire organ, and thought a dilated stomach could be shrunk greatly by methods of medical treatment.

DR. HENRY D. BEYEA, Philadelphia, referred to an operation that he had devised, which consisted simply in shortening the normal ligaments. It was unassociated with danger and non-mutilating.

DR. BLOODGOOD stated that the indication for operation in his case was the fact that the patient had residuum. He had been surprised at the extreme degrees of ptosis that might be present without producing symptoms. His case was not one in which he would have wished to try suture of the ligament alone.

SOME LEADING POINTS IN X-RAY EXAMINATION OF THE DIGESTIVE TRACT; LANTERN-SLIDE DEMONSTRATION.

DR. P. M. HICKEY, Detroit, emphasized the following points: (1) That it is exceedingly unwise to form opinions from the Röntgen examination without due consideration of all the factors in the case; (2) that though a fluoroscopic examination of the gastro-intestinal tract offers certain advantages, yet the inherent danger at the present time does not warrant its wide application; (3) that a stereoscopic method of examination offers certain advantages in selected cases; (4) that by the use of plates made at succeeding intervals after the bismuth meal, the diagnosis and degree of pyloric insufficiency can be determined; (5) that the position of the stomach as found at operation or autopsy does not correspond with the position of the stomach when the patient is in the erect position and when it is filled with food; (6) that the mobility or immobility due to adhesion of the colon can be determined by a careful comparison of the plates made in the erect, horizontal and Trendelenberg positions.

(*To be continued.*)

## Book Reviews.

*Dyspepsia.* Its Varieties and Treatment. By W. SOLTAU FENWICK, M.D. (Lond.), Doctor of Medicine of the University of Strassburg; late physician to the Evelina Hospital for Sick Children, etc. Illustrated. Pp. 485. Philadelphia and London: W. B. Saunders Company. 1910.

Fenwick's work is the result of a large and intimate experience in the treatment of digestive disorders. It is an attempt to describe, to explain and to differentiate the numerous classes of cases where dyspepsia is the common complaint, and to apply rational treatment to each. In the first chapter a classification is given, including gastric indigestion of different forms, and intestinal indigestion. The sub-headings under gastric indigestion are: Disorders of secretion; disorders of motility; disorders of the nervous mechanism; dyspepsia due to inflammation of the stomach; dyspepsia due to displacements of the stomach; dyspepsia due to the presence of foreign bodies and living creatures in the stomach; dyspepsia peculiar to infancy and old age; and dyspepsia due to diseases of other organs. The better known disorders such as hyperacidity, hypersecretion and achylia gastrica are discussed without notable variations from established teachings. Other disorders, however, notably myasthenia gastrica (atony) and dyspepsia due to foreign bodies, are given prominence greater than is consistent with prevailing opinion. Also little attention is directed to the occurrence of latent gastric and duodenal ulcer, the possibility of which has of late years been shown to be so great. The volume gives the reader an impression that the diagnosis of the type of disease is easy and certain in excess of common experience. The work is of value, however, as a description of observations upon a large number of patients, and especially in the detailed recommendations for practical treatment.

*Essentials of Laboratory Diagnosis.* Designed for Students and Practitioners. By FRANCIS ASHLEY FAUGHT, M.D., Director of the Laboratory of the Department of Clinical Medicine and Assistant to the Professor of Clinical Medicine, Medico-Chirurgical College, etc., Philadelphia, Pa. Containing an indican scale in colors, 8 full-page plates and numerous engravings in the text. Pp. 328. Second revised edition. Philadelphia: F. A. Davis Company. 1910.

Faught's manual aims to embody the essentials of laboratory diagnosis without unnecessary elaboration, but with sufficient detail to insure clearness. While such elementary details as the use of the microscope are duly described, full directions are also given for the performance of complicated and new diagnostic methods, such as the Wassermann and the Noguchi serum reactions. The successive chapters deal with the use of the microscope, sputum, blood, the opsonic method, blood pressure, coagulation, blood parasites, animal parasites, determination of the functions of the stomach, feces, urine, cerebrospinal fluid, other body fluids, human milk, bacteriologic methods, serodiagnosis, and the equipment and management of a clinical laboratory. Directions are given in such a way that one unfamiliar with medical laboratory procedures might well acquire proficiency in the common tests without other source of instruction. Those whose knowledge of laboratory methods includes only the older methods will undoubtedly find this manual useful in acquiring familiarity with more advanced laboratory diagnosis. As is necessary in the preparation of a work which describes so much within small compass, chief attention is given to the description of methods practiced by the author rather than to discussion of the various methods in use by different workers. While in a few instances matters that might well be included are not mentioned, and other matters are awarded a prominence that is not generally granted, at least one good way of attaining each object is fully set forth, and one who follows the directions may be confident of his results.

## THE ORIGIN OF THE OFFICE OF CORONER.

In the issue of the *British Medical Journal* for May 6 is an interesting abstract of a paper by Dr. F. J. Waldo on "The Origin of the Ancient Office of Coroner." It seems probable that the office was established under Henry I of England, but the earliest known authentic reference to it is in Chapter 20 of the Articles of 1194, providing for the election by each county of three knights and one clerk as "custodians of the crown pleas." It was the duty of these "custodians" to keep a record of all pleas, suits or causes which more particularly affected the king's crown and dignity, especially in connection with the administration of criminal justice. One of the chief objects of doing this, apparently, was to secure for the king any treasure or plunder that might be forfeited to him; hence Bracton, in describing their office, says, "They ought immediately to visit the slain, or the wounded, or the drowned, or those who have died suddenly, and the breakages into houses, and the places where treasure was said to have been found." Thus from this early office of "keeper of the king's pleas" (*custos placetorum coronae*) developed that of coroner or crowner, with a name derived from the Latin title, but with functions much more extensive than those of the modern medical examiner.

In Britton's manual of law, published in 1291, it is stated that the coroner is "a principal guardian of the king's peace, bearing record of the pleas of the crown, of his own views on inquests, and of abjurations and outlawries. He is bound to inquire concerning treasure-trove, wreck, whales, and sturgeons, and to secure them for the king's use." His functions were both judicial and administrative and extended also to cases of rape, arson, sodomy and "infant monsters who had nothing of humanity or who had more of the beast than the man in them, and these the coroner caused to be buried; but the holy faith groweth stronger every day, whereby folk do not burden their souls with such horrible sins so commonly as they used." This bit of contemporary evidence as to the supposed cause of fetal monstrosities, and testimony as to their declining frequency, is most instructive. In all matters that came under the coroner's jurisdiction, his decision was absolute, and there was no appeal from "crowner's quest law." In process of time his duties have become purely medico-legal, but the persistence of the office in all English-speaking communities is evidence of the racial conservatism which has been one of the strongest traits of the Anglo-Saxon.

## LUCRETIUS AND THE PLAGUE.

In the issue of the Journal for April 20 we published an editorial on "Thucydides and the Athenian Epidemic of Plague." A recent number of the *Münchener Medizinische Wochenschrift* calls attention also to "The Clinical Picture of the Plague in Lucretius."

At the end of the sixth book of his "*De Natura Rerum*," the epicurean Lucretius presents in hexameters a consideration of the supposed causes of various pestilences. After briefly describing elephantiasis as endemic in Egypt and trachoma in Achaia, he says of the plague in Attica:

"A mortal, febrile disease once devastated the streets of Athens. At first the victims suffered from burning headache. The eyes became red and inflamed. Mouth and pharynx were injected and beset with ulcers. The tongue was parched. The pains were intolerable. The disease burned inward to the bones; the stomach glowed like an oven. The patients, suffering with unquenchable thirst, would plunge head-first into water cisterns. Medicine was powerless to aid them. Sleepless and helpless, they rolled in agony till death came to relieve them by gangrene or convulsions."

Perhaps the poet exaggerated this horrible picture, after the license of his kind. At all events, it is an interesting piece of classic evidence as to the nature of this great scourge. Lucretius was a contemporary of Cicero, and whether he himself ever saw an epidemic of the plague is uncertain. Livy mentions that the plague broke out in Rome in 430 B.C., and was extensively epidemic in Africa in 130 B.C. It seems probable, even though he had no immediate knowledge of it,

that Lucretius was familiar with the general aspects of a disease whose visitations in his time were fairly frequent, and that his poetic imagination has not led him far astray in the depiction of its clinical symptoms.

## PLOT TO ASSASSINATE PRISON OFFICIALS.

A remarkable plot among the inmates of the State Hospital for Insane Criminals at Matteawan, to assassinate the superintendent and first assistant physician of that institution, has been disclosed in a report just made public, presented to the governor by William Church Osborn, the governor's legal adviser, and Mayor Van Kennen, of Ogdensburgh, who were appointed special commissioners to examine into the affairs and management of the state prisons and reformatories. The plot originated with an Italian patient, a homicidal paranoiac, who, in common with the other inmates, was examined by Drs. Carlos F. MacDonald and Austin Flint, of New York, who were engaged by the commissioners to investigate the mental condition of those confined in the hospital, especially with a view to ascertain whether there was any truth in certain reports which had been circulated to the effect that some persons who were really sane were being held as prisoners there. It is shown that there actually was a conspiracy involving a number of the inmates (certainly a rare combination among insane patients), who had contrived to arm themselves for a common purpose, — the murder of the officials named.

Drs. MacDonald and Flint, as the result of their investigations, made a number of recommendations, among which were the following: That a more rigid discipline should be maintained at the Matteawan Hospital; that the hospital be taken out of the jurisdiction of the State Prison Department and placed exclusively under the control of the State Commission in Lunacy (at present the authority over the institution is divided between these two departments); and that the original theory of maintenance of the institution as a hospital for insane convicts should be changed and that it should be regarded, not as a state hospital for the insane of a special class requiring specialized attention, but as an institution substantially similar to other state hospitals for the insane. They state that though this hospital was originally used for the care of the insane during their term of sentence, they find that the character of the inmates has changed, the bulk of the insane persons under sentence being now maintained at Dannemora Hospital, while the inmates of Matteawan are either those known as "court order" cases, that is, persons accused of a crime and found before conviction to be insane, or persons convicted of some offense whose terms have expired but who are detained because of insanity. They believe that, by following the plan suggested, a larger proportion of cures will result, and that the public attitude of question and suspicion of the management of the institution will be relieved. They, therefore, recommend that the insane persons subject to a prison term who are now in the Matteawan Hospital be transferred to Dannemora, proper provisions being made, and the law so amended that the Matteawan Hospital will be put under the jurisdiction of the State Commission in Lunacy.

The two alienists were able to examine without difficulty seven hundred and sixty-one of the seven hundred and ninety-three inmates. Among the thirty-two who declined to be examined was Harry Thaw, who killed Stanford White, but it is stated that he conducted himself in their presence in such a manner as to leave no doubt of his unbalanced mental condition. The commissioners also engaged the services of Goodwin Brown, who was a member of the State Commission in Lunacy for ten years, and they state in their report that, from their own personal inspection, from the reports of Mr. Brown and of Drs. MacDonald and Flint, and from the outcome of an investigation conducted by the district attorney of Dutchess County (in which the Matteawan Hospital is situated), they are satisfied that no unusual conditions of violence or depravity exist in this institution, and that no patients who are in such condition of sanity as to warrant their discharge are detained there beyond the usual time needed to determine the conditions in each case.

## THE WATER-SUPPLY OF BOSTON.

IN an editorial on "The Metropolitan Water and Sewerage Board," in the issue of the JOURNAL for April 27, we commented on "the present importance and value to the public health" of the extensive works undertaken by the Water Board for the service of Boston and its adjacent towns. The great value of an adequate and reliable water-supply is emphasized at the present time by contrast of the favorable situation of Boston with the drought and impending water-famine now prevalent in other and less fortunate parts of this state and elsewhere. It will be

remembered that last fall there was a serious shortage of drinking water in many towns of western Massachusetts, and this condition bids fair to recur unless there be very early and abundant rains. Unless the situation is thus relieved, serious epidemics of water-borne disease may be expected from deterioration in the quality as well as the quantity of the supply in many regions.

The fortunate position of Boston in respect of water-supply is due to the wisdon and foresight of the Metropolitan Water Board, which fifteen years ago began the establishment of a system sufficient to supply our community for years to come. The board should receive not only gratitude for this service, but support in other measures of public utility which it may advocate.

## HARVARD SCHOOL FOR ADVANCED INSTRUCTION IN MEDICINE.

The Harvard Corporation voted, on May 10, to approve the establishment, in accordance with a plan recently proposed by the Faculty of Medicine, of a School for Advanced Instruction in Medicine. The Overseers at a later meeting consented. It is intended that this new school, which is to be under the direction of a separate dean and administrative board, shall go into operation at the beginning of the academic year 1912-13, that it shall supersede the present graduate instruction and shall ultimately absorb the Summer School of Medicine. Courses will be offered either as all-day courses in general or special subjects or as intermittent courses for students "who live nearby and who want instruction for a part of one or more days in the week," or as research courses for those who wish to do original investigation. The instruction will be provided by existing departments in the school if possible, but if not, new instructors may be appointed, with the title of Lecturer or Fellow. The project for this new school seems full of promise and should establish upon a permanent basis the importance and efficiency of graduate medical instruction in Boston.

## A HOSPITAL FOR PRIVATE PATIENTS.

Public announcement has been made of a proposed hospital in Boston to be devoted solely to the care and treatment of private patients. It has long been an anomaly in our hospital system that the patient who is an object of charity has been provided with greater facilities for the completest treatment than the patient who is both willing and able to pay for such service. The tendency has been for the development of great hospitals under private or municipal control devoted to purely charitable ends. The public interest in these hospitals has been such that their equipment has far surpassed anything hitherto possible in the small hospitals designed for the care of persons able to pay for their residence and treatment. In spite of their necessarily imperfect equipment, the demand made upon these smaller private hospitals has amply demonstrated the need of a larger hospital, in which may be brought under one roof and management the same facilities which are common to our great public charitable institutions. To this end a body of business men and physicians, representing on the one hand the financial interest and on the other the medical profession, and together acting as directors, have proposed and made public a plan to construct and administer a comprehensive hospital for private patients which shall place within the reach of the well-to-do the same advantages which are now offered only to the poor. An outline of the plan has already been published in the Boston *Evening Transcript* of May 22, to be followed by a full prospectus within a week. It should be understood that this hospital, if constructed as designed, is to be thrown open freely to all reputable members of the medical profession, with the same privileges as apply to the physicians who act as incorporators. It is not to be questioned that the time is ripe for such an enterprise as this, and that such a hospital will fill a distinct need in the community, which is rapidly coming to a realization that many, if not all, forms of disease may be more adequately and successfully treated in a hospital than at home. The medical profession and the laity will doubtless look forward with equal interest to the consummation of this unique but entirely reasonable project.

## MEDICAL NOTES.

Smallpox and Bubonic Plague at Amoy. — Report from Amoy, China, states that during the fortnight from May 5 to May 19, there were in that city 43 deaths from bubonic plague and 6 from smallpox.

Yellow Fever in Colombia. — It is reported from Bogota, Colombia, that yellow fever is epidemic in the city of Bucaramanga, capital of

the department of Santander in that country. Sixty cases are said to have occurred during the week ending May 18.

Honorary Degree for Professor Richards. — It is announced from London that the University of Cambridge, England, will confer the honorary degree of LL.D. on Theodore W. Richards, Ph.D., S.D., M.D., professor of chemistry in Harvard College, and now filling the Faraday lectureship in London.

Injury to Professor Haeckel. — It is reported from Jena, Germany, that Dr. Ernst Heinrich Haeckel, professor of zoölogy at the University of Jena, and celebrated for his embryologic researches, sustained a fracture of the neck of the femur on May 16, by falling from a high stool in his library. Professor Haeckel is now seventy-seven years of age.

London Death-Rates in March. — Statistics recently published for March, 1911, show the death-rate for that month in London to have been 16 per 1,000 living. Among the several districts and boroughs the highest rate was 26.0 in Shoreditch, at the east end, and the lowest 8.9 in Hampstead, an open suburb.

Medal Awarded to a Physician's Widow. — Report from Paris states that, on May 16, the Carnegie Fund Committee of France awarded the Foundation gold medal to the widow of Dr. G. E. Mesny, a French physician, who died of the plague on Jan. 12 at Harbin, Manchuria, during the recent epidemic of the disease in that country.

French Vital Statistics for 1910. — Statistics published in the *Journal Officiel*, on May 18, by Dr. Jacques Bertillon, of Paris, indicate that during the year 1910 there were in France 309,289 marriages, 13,049 divorces, 703,777 deaths and 774,358 births. This is the smallest number of births that has occurred in France since 1810. In 1859, there were 1,018,000 births; in 1862, 984,000; in 1887, 899,000. The excess of births over deaths in 1910 was only 70,581, whereas the excess in Germany during the same year was 884,061.

Bequests to Medical Institutions. — The will of the late S. Herbert Howe, of Marlboro, Mass., who died on May 11, was filed last week in the probate court at East Cambridge, Mass. Among several charitable bequests it contains one of $2,000 to the Marlboro Hospital.

The will of the late Dr. Charles A. Oliver, of Philadelphia, contains bequests of $5,000 each to the Wills Eye Hospital and to the College of Physicians of Philadelphia.

American Society of Superintendents of Nurses. — The annual meeting of the American Society of Superintendents of Training Schools for Nurses will be held in Boston on May 29, 30 and 31. At the session on May 29, there will be addresses by Miss Mary M. Riddle, superintendent of the Newton (Mass.) Hospital, and Miss Sara A. Parsons, of the Massachusetts General Hospital; on May 30, by Miss Clara D. Noyes, of the Bellevue Hospital, and Miss J. C. Stimson, of the Harlem Hospital, New York. In the evening of May 30, Dr. Frederick S. Lee, of Columbia University, will deliver a lecture on "Fatigue in Relation to Health and Efficiency." On May 31, there are to be demonstrations at the Massachusetts General Hospital, and in the evening a dinner given by the Massachusetts State Nurses' Association.

Philadelphia Milk Exhibit. — On Saturday, May 20, there was opened in Philadelphia an extensive "milk exhibit," under the co-operative management of the City Department of Public Health, the Philadelphia Pediatric Society, the Veterinary Department of the University of Pennsylvania and the Bureau of Municipal Research. The purpose of the exhibit is to demonstrate the best methods of production, transportation and distribution of milk. In conjunction with it will be held meetings of the American Association of Medical Milk Commissions, the Certified Milk Producers' Association of America and a conference of municipal health officials. There will be numerous daily lectures and demonstrations by physicians and others from this country and from Canada.

Further Note on Case of Nerve "Fusion" in the Issue of Journal, May 11, 1911. — At the date mentioned above, Dr. Henry Feiss, of Cleveland, Ohio, reported a case of infantile paralysis of about five years' standing affecting the internal popliteal, in which a nerve "fusion" was carried out on the popliteals. Up to the time of the last visit mentioned in that report, Feb. 16, 1911, it seemed that a new distribution of muscular power might be taking place, but at a subsequent date, when the case was last seen, May 6, 1911, the case presented about the same characteristics as before the operation. If there was any functional improvement, it was so slight as to be unimportant. In order to leave no false

impression, the author prefers to consider the operation a failure up to the last date mentioned, although there is, perhaps, still a little chance for improvement. The patient is, however, no worse than before the operation. If any further nerve "fusions" are attempted, patients will be selected, the author states, in whom the paralysis is of more recent standing.

## BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, May 23, 1911, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 37, scarlatina 31, typhoid fever 5, measles 176, smallpox 0, tuberculosis 53.

The death-rate of the reported deaths for the week ending May 23, 1911, was 18.09.

Boston Mortality Statistics. — The total number of deaths reported to the Board of Health for the week ending Saturday, noon, May 20, 1911, was 231, against 214 the corresponding week of last year, showing an increase of 17 deaths, and making the death-rate for the week, 17.48. Of this number 122 were males and 109 were females; 225 were white and 6 colored; 148 were born in the United States, 79 in foreign countries and 4 unknown; 58 were of American parentage, 142 of foreign parentage and 31 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 48 cases and 1 death; scarlatina, 35 cases and 3 deaths; typhoid fever, 6 cases and 0 deaths; measles, 169 cases and 1 death; tuberculosis, 68 cases and 20 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 30, whooping cough 2, heart disease 20, bronchitis 2. There were 29 deaths from violent causes. The number of children who died under one year was 42; the number under five years, 61. The number of persons who died over sixty years of age was 63. The deaths in hospitals and public institutions were 105.

Change in West End Call Station. — It is announced by the Boston Dispensary that the West End call station of the district physician has been changed from 44 Chambers Street to the Elizabeth Peabody House at 87 Poplar Street.

Graduating Exercises of Boston City Hospital Training School. — The graduating exercises of the class of 1911 of the Boston City Hospital training school for nurses will be held at 4 P.M. on Friday, May 26, in the surgical amphitheater of the hospital. There will subsequently be a reception in the Vose House. The graduating class this year consists of thirty-eight pupils.

Massachusetts College of Pharmacy. — The annual class day and commencement exercises of the Massachusetts College of Pharmacy were held in Boston last week. The degree of doctor of pharmacy was conferred on sixteen candidates, two of whom were women.

A Death from Smallpox in Boston. — The death of an infant from smallpox was reported in Dorchester on May 16. The house in which the case occurred has been fumigated, and all persons who came in contact with the patient have been quarantined and vaccinated by the Boston Board of Health.

Address by Dr. Pearce. — On the afternoon of Thursday, May 18, Dr. Richard Mills Pearce, professor of research medicine in the School of Medicine of the University of Pennsylvania, delivered at the Harvard Medical School an address on "Experimental Medicine; Its Influence upon the Teaching of Medicine," before the Massachusetts Alpha Chapter of the Alpha Omega Alpha Society.

An Epidemic of Tonsillitis. — During the past fortnight, tonsillitis has been extensively prevalent in Boston and its vicinity, and also to the westward. It is estimated that over two thousand cases have occurred. Without adequate apparent evidence, this epidemic has been attributed to infected milk. It seems much more likely to be due to the dust, heat and high winds that have lately prevailed in both eastern and western Massachusetts.

Report of Boston Infirmary Department. — The fourteenth annual report of the Infirmary Department of the City of Boston contains the record of work done at the Long Island Hospital, and in the almshouses at Long Island and at Charlestown, during the year ending Jan. 31, 1911. There have been 881 inmates at Long Island during the past year and 102 at Charlestown. Twenty-one nurses were graduated from the training school. The trustees recommend the immediate authorization and construction of a hospital addition to accommodate two hundred patients.

Report of Worcester Board of Health. — The annual report of the Board of Health of the

city of Worcester, Mass., for the year 1910, which has just been published, records the vital statistics of the city for that year and presents an interesting record of the activities of the board in health inspection, routine bacteriologic examinations and the investigation and quarantine of infectious diseases. There are appended special reports of the resident physician of the isolation hospital and of the inspector of milk. The publication is a succinct statement of the details of the hygienic administration of a city community.

APPOINTMENTS BY THE BOSTON BOARD OF HEALTH. — It was announced last week that the Boston Board of Health has appointed Dr. Thomas J. B. Dillon, of Roxbury, as medical inspector, "to examine all children under sixteen years of age who apply for certificates allowing them to go to work." Dr. Dillon received his medical degree in 1884 from the Royal College of Physicians and Surgeons, Dublin.

It was also announced that the board has voted to appoint Dr. Francis H. Slack, of the University of Kansas, as secretary to the board, in the place of Mr. Charles E. Davis, Jr., who is soon to retire under the recent act for pensioning city officials. Dr. Slack has formerly served as director of the laboratory of the Boston Board of Health.

CONCORD DEACONESS HOSPITAL. — In a recent issue of the JOURNAL we noted a generous gift of land and money for the erection of a Deaconess Hospital at Concord, Mass. On May 17, a public meeting was held in the Concord town hall to stimulate general interest in this new building. Dr. Edward W. Emerson, of Concord, presided, and addresses were made by Dr. Maurice H. Richardson, of Boston, and Dr. Alfred Worcester, of Waltham, Mass. "The hospital, which is now in process of erection, is of semi-fireproof construction, its walls and floors being made of glazed terra cotta tile and concrete. Located on one of the highest points in the near vicinity of Concord, it has a splendid outlook in every direction. The building will provide an operating suite, administration offices and room for eleven beds on the first floor, dining room, kitchen and other accommodations in the basement and nurses' home on the second floor. It is expected during the warm months the capacity of the hospital will be augmented by the use of tents. Within a radius of seven miles of the hospital are seven communities which will be privileged to use its facilities."

## NEW YORK.

THREE BEQUESTS TO HOSPITALS. — Among the charitable bequests in the will of the late Martin Herman, of New York, are $5,000 each to the Montefiore Home and Hospital for Chronic Invalids and the Mount Sinai Hospital and $1,000 to the Beth Israel Hospital.

APPROPRIATION FOR FILTRATION PLANT AT JEROME PARK. — On May 11, the Board of Estimate and Apportionment appropriated $8,690,000 for the completion of the eastern basin of the Jerome Park reservoir and the installation there of a great filtration plant. The establishment of this plant has long been desired, and the matter was repeatedly urged by Dr. Darlington when he was president of the Board of Health.

SUPPOSED DEATH FROM EATING ICE CREAM. — The recent death of a little girl two years old at Yonkers is believed to have been due to poisoning from eating an ice cream sandwich, bought from a street vender. Two companions, aged respectively five and six years, who also partook of the ice cream, have been in St. John's Hospital suffering from ptomaine poisoning.

APPOINTMENT OF DR. LUCAS AT MUSEUM OF NATURAL HISTORY. — The trustees of the American Museum of Natural History have appointed Dr. Frederick Augustus Lucas director of the museum. Dr. Lucas, who is at present chief curator of the Brooklyn Institute of Arts and Sciences, is a native of Plymouth, Mass., and in 1882 was appointed osteologist at the United United States National Museum. At this institution he was made curator of the department of comparative anatomy in 1893, and director of the department of biology in 1902. In 1904 he received the appointment of curator-in-chief of the Brooklyn Institute. He is especially known as the author of several publications on North American mammals.

OPENING OF DEPARTMENT OF PUBLIC HEALTH. — On May 15 a Department of Public Health was inaugurated at the American Museum of Natural History, and at the same time there was opened in one of the wings of the building an exhibition showing the work and plans of the Metropolitan Sewerage Commission, to be on public view for a month. Among those who made addresses on this occasion were Calvin Tomkins, commissioner of docks and ferries,

representing Mayor Gaynor; Dr. Soper, president of the sewerage commission; Professor Winslow, curator of the public health department of the museum; and Dr. Harvey W. Wiley, of Washington.

Death from Broken Neck after Twelve Years. — Among other charitable bequests in the will of Walter E. Duryea, formerly of Glen Cove, Long Island, N. Y., who died recently after having survived for twelve years with a broken neck, are $15,000 to the Roosevelt Hospital, as a memorial to his father and mother; $5,000 to the Nassau County Hospital, at Mineola, Long Island; $7,000 to the Mountainside Hospital, at Montclair, N. J.; and $2,000 to the Montclair Fresh Air and Convalescent Home. Mr. Duryea met with his accident in making a dive in shallow water at Oyster Bay in 1899, and his case attracted unusual interest at the time. As his family were wealthy, he had every possible advantage in the way of care. He was taken to Roosevelt Hospital, where after consultation with eminent neurologists he was operated on by Dr. Robert F. Weir, assisted by other prominent surgeons. The principal legatee of Mr. Duryea's estate, it is interesting to note, is Miss Eleanor Peregrine, who was one of his nurses at Roosevelt, and who has devotedly attended him ever since he left the hospital.

A Physician's Golden Wedding. — On May 15, there was celebrated the golden wedding of Dr. Louis A. Rodenstein, a prominent practitioner long identified with the Washington Heights section of the city. Mrs. Rodenstein comes of a very long-lived family, in which there have been, including her own, six golden weddings during the last sixty years. She is a grand-niece of Peter Cooper and the daughter of the late Daniel F. Tiemann, who was mayor of New York in 1857 and 1858, and both her parents lived to the age of ninety-three. Dr. Rodenstein was born at Frankfort on the Main, and was brought to this country when eight years old. The family settled at Austin, Tex., and while there he attended the school of Dr. Anson Jones, who was the last president of the Republic of Texas. He was graduated from the medical department of the University of Pennsylvania in 1859, but has spent all his professional life in New York. He was one of the founders of the Manhattan Hospital, on 131st Street, now the J. Hood Wright Memorial Hospital, and until a few years ago remained on its attending staff.

8. Dawbarn, R. H. M. *Short Talks with my Students and Others: Being Random Suggestions for the Younger Practitioners.*

3. Rosanoff reviews the prophylactic measures against insanity which have been practiced with some success. The causes of insanity are essential and contributory. The essential causes are heredity, alcohol, syphilis, head injuries. To prevent bad heredity, laws prohibiting the marriage of defectives have been enacted in certain states, and some benefit may have been derived from such legislation. Measures for the prevention of conception — vasectomy, salpingectomy, castration — have been practiced with satisfactory results. For the prevention of alcoholism, three systems have been partially effective: (1) the Gothenburg system in Sweden, (2) prohibition, (3) local option. The prevention of syphilis is closely limited to the control of prostitution. Prophylactic treatment has been of almost unfailing efficacy according to the reports of some medical officers of the United States Navy. To prevent head injuries little can be done save in protective legislation to diminish the number of serious accidents.

The contributory causes of insanity are innumerable, especially frequent being unhappy love affairs, pregnancy, abortion, childbirth, lactation, overwork, worry, fright, grief. Prophylaxis here is difficult. For the neuropathic individual every feature of life presents possible dangers. From childhood up the adjustment between him and his environment must be nicely controlled. The recognition of the neuropathic makeup is obviously of the highest importance. [L. D. C.]

8. MENDENHALL, A. M. *Chemical Dermatitis from Incompatible External Applications.*
9. BROWN, I. *A Peculiar Case of Intestinal Obstruction.*

1. Dercum believes that the rôle of dreams in etiology is a very doubtful one. They are probably always symptomatic and never causal and their symptomatic value is of little consequence.

3. Cramp reports an interesting case of chronic glanders in man, which was apparently successfully treated by a glanders vaccine. Cases of chronic glanders are easily overlooked. Multiple abscesses, especially on the extremities without definite cause, should excite suspicion, as in 80% of these cases, multiple abscesses occur. Extreme exposure to bad weather seems to be a predisposing cause. No direct association with horses was demonstrable in Cramp's case.

7. Risley, working with body fluids such as hydrocele, spermatocele and ascitic fluids from cases of cirrhosis of the liver or incompetent heart, and then with ascitic fluids from resistant cases of cancer of the ovary and peritoneum and liver, has found that the cancerous fluids, in a large per cent of cases, act beneficially on the cancer patient and his tumor. Three things are especially noticeable: (1) Relief from pain; (2) retardation of the growth from one to eight months; and (3) a general improvement in the condition of the patient. These results were not obtained even with large doses of the non-cancerous fluids. There is nothing curative in the cancerous fluids, but as a reliever of pain, and in producing other symptomatic improvement, the treatment is valuable. [E. H. R.]

9. GAGE, J. G. *A Case of Strongyloides Intestinalis with Larvæ in the Sputum.*

1. Emerson reports clinical observations of blood pressure in tuberculous individuals and experimental results with tubercle products on cats and dogs. He finds hypotension so important that it should be sought for as carefully as pulmonary signs are in suspected cases. A failure of normal cardiovascular response to exercise or change of position often indicates susceptibility to tubercular infection. The causes of low blood pressure in tuberculosis are probably primarily a toxic action on the vasomotor center in the medulla, and secondarily progressive cardiac atrophy or degeneration. The secondary anemia with its diminished albumin, salts and hemoglobin content serves to add to the hypotension from purely physical causes in the blood stream. The result of hypotension in tuberculosis or in any other condition is insufficient capillary pressure, more or less venous stagnation and insufficient nourishment with resulting atrophy or degeneration of the essential organs of the body. The treatment of tuberculosis should take into consideration the need of assisting in every way the return to normal pressure. Prognosis can as safely be based on the alteration in the blood pressure as on changes in the pulse or temperature.

4. Rohdenburg, Bullock and Johnston conclude as follows from an experimental and clinical investigation of the relations between certain internal secretions and malignant tumors: (1) Removal of the thyroid, thymus and testes appears to decrease the susceptibility to cancer; (2) removal of glands in immune animals leads to lessened immunity to cancer; (3) extracts of thymus, thyroid, spleen, pancreas, pituitary and testes on injection tend to increase immunity against cancer; (4) similar extracts, on injection into cancerous organisms, alleviate pain, reduce tumors and even cause them to disappear; (5) many tissues contain some common element which is capable of producing immunity.

1. *Cf. British Medical Journal*, April 22, 1911.

2. Mackenzie, in the second of the Oliver Sharpey Lectures on heart failure, speaks on the estimation of heart failure and the significance of symptoms. He first reviews the essential factors in maintaining circulation, the nature of the heart's functions and the bearing of disease processes on the heart's work. He then discusses the symptoms of beginning heart failure, (1) due to changes in the organ itself, (2) due to impaired function, and (3) those due to reflex stimulation of other organs. In estimating the heart's strength, he emphasizes the fact that each individual has his own standard by which his heart must be gauged; he discusses the difference in the significance of various symptoms in various individuals. The simplest test of cardiac strength or failure is how it responds to effort. He calls attention to the inadequacy of many of the present methods of measuring heart strength and urges the greatest attention to how the heart of any person responds to the stress and strain of daily life as the best and safest guide to its real efficiency. [J. B. H.]

APRIL 22, 1911.

1. *LANE, W. A. *A Clinical Lecture on the Kinks which Develop in our Drainage System in Chronic Intestinal Stasis.*
2. *CHAPPLE, H. *Chronic Intestinal Stasis Treated by Short-Circuiting or Colectomy.*
3. *ALLBUTT, C. *An Address on Arteriosclerosis and the Kidneys.*
4. MCKENZIE, I. *On the Interdependence of the Circulatory and Respiratory Systems.*
5. WARD, G. R. *Hepatic Distomiasis (Sheep Rot) in Man.*

1. Lane discusses the various kinks developing in certain places in the bowel, notably in the vicinity of the jejunum, near the ileum and at the hepatic and sigmoid

flexures of the colon. These so-called kinks are generally due to intestinal stasis by means of which strain is produced and "peritoneal bands" are formed. He discusses the surgical treatment of this condition.

2. Chapple presents the details of fifty cases of chronic intestinal stasis on which he has operated, making a short circuit usually from the ileum to the iliopelvic colon. In these cases the site of the obstruction, usually due to sagging of the transverse colon, was at this point. The symptoms complained of by these patients were the ordinary ones of constipation. On examination there were painful points over the "abnormally *fixed*" portion of the bowel, and the transverse colon was "usually palpable and hung below the level of the umbilicus." He describes the nature of the operation and his results.

3. Allbutt, discussing arteriosclerosis and the kidneys, first dwells upon the present confusion of ideas and lack of accord in terminology of this condition. He briefly reviews the work previously done on the subject and compares and comments on the opinions of the present day. He discusses in considerable detail the morbid anatomy found in various chronic kidney and arteriosclerotic conditions; he considers the relation of Bright's disease and high pressure, the effect of various infections on the kidneys, nervous factors entering into the problem and the part played by the adrenals. He endeavors to draw a sharp line between the conditions he calls chronic Bright's disease and others largely due to arteriosclerosis which he does not consider as true Bright's disease. [J. B. H.]

13. Kuhn, F. *The Transportable Litter-Bed.*
14. Fülleborn. *Observations on Dr. V. Reichmann's "Unusual Filarial Disease. Cure by Salvarsan."*

1. Wilms describes a new method of narrowing the thorax for chronic phthisis. He cuts through the muscles of the back and resects pieces of the ribs. By this method more narrowing is obtained than by resection anteriorly because the costal cartilages allow of considerable movement. Also, the first rib is more easily accessible. He reports one case which did well.

2. The writer says that he has had experience in 250 cases of intravenous narcosis. He recommends particularly a combination of isopral narcosis with ether narcosis, both being used intravenously, and he considers ether preceded by scopolamin-morphine to be nearly as good. The contra-indications are myocarditis, severe arteriosclerosis, nephritis, severe icterus, cholemia, passive congestion and plethora. The more important indications are collapse, severe hemorrhage, cachexia, exhaustion, disturbances of respiration, peritonitis and operations on the head and neck.

5. Christen describes a new instrument for estimating the force of the pulse wave. He first determines the mean blood-pressure and then the volume of the pulse wave by reading a manometer. These multiplied together give the energy value of the pulse. He thinks the instrument will prove to be of great usefulness clinically for comparative work. [G. C. S.]

4. *UNGAR, K. *Case Contributions to Banti's Disease.*
5. FRAENKEL, A. *The Problem of Cancer.*
6. SOFER, L. *Social Medical Review.*

4. From a study of three cases of Banti's disease, which he reports, Ungar reaches the following conclusions:

(*a*) That Banti's disease is an independent clinical entity, whose primary cause lies in the gastro-intestinal canal, which at first expresses itself in enlargement of the spleen, with consecutive interstitial inflammation of the liver, with all its consequences, and produces a characteristic change of the blood.

(*b*) That syphilis, tuberculosis and alcoholism play no important part in the etiology of the disease.

(*c*) The third, or ascitic, stage, may last for more than a year.

(*d*) A cure of Banti's disease in the third stage, by extirpation of the spleen, has little probability, since the body retains only slight powers of resistance against infection of the peritoneum, lungs and so forth. [R. M. G.]

1. *Metchnikoff, E., and Besredka, A. *Researches on Experimental Typhoid Fever.*
2. Armand-Delille, P., and Launoy, L. *Study of the Stabilization of the Red Blood Corpuscles of Mammals (of the Sheep in Particular) in Very Dilute Solutions of Formalin.*
3. Chonkevitch, J. *Study of the Bacterial Flora of the Large Intestine of the Horse.* (To be continued).
4. Crendiropoulo. *The Mechanism of the Bordet-Gengou Reaction. The Rôle of the Antihemolysins of Sera.*

1. As a result of their experiences upon apes and monkeys, these authors conclude that it is possible to produce experimental typhoid fever. Of the animals used, only the anthropoids are susceptible to infection by mouth. In exceptional cases the lower monkeys are capable of becoming infected. Rodents and rabbits, however, are refractory towards this infection. The typhoid fever in the anthropoids is produced by the pure cultures of the bacillus of Eberth. It cannot be produced by the filtrate. These authors warn against confusing the peritonitis caused by intraperitoneal injection in rodents with a true typhoid fever. The protection by means of vaccines against this peritonitis does not suffice to protect against the experimental typhoid fever. [C. F., Jr.]

5. Pezzi, C. *Bibliographical Note.*

1. Sabella reports two cases of malaria in pregnant women, one of whom died in a paroxysm, the other aborting at the fourth month. Careful post-mortem examination in each case failed to demonstrate malaria in the fetus. The author, therefore, doubts the transmissibility of the malarial parasite through the placenta. [L. D. C.]

## Miscellany.

### THE USE OF DIGIPURATUM IN HEART DISEASE.

Wm. F. Boos, L. H. Newburgh and H. K. Marks, in a paper published in the April issue of the *Archives of Internal Medicine*, discuss the great differences observed in the pharmacological strength of digitalis leaves and their preparations. The efficiency is said to depend greatly upon the soil, the gathering season, the method of collecting and drying the leaves and the methods used in preserving the dried product. For a time it seemed as if the pure active principles of digitalis would be reliable substitutes for the galenical preparations, but it was soon evident that neither digitalin nor digitoxin alone could produce the true digitalis effect obtainable from the leaf preparations. These facts show the need of leaf preparations of known strength. As the fluid preparations do not retain their original strength so readily, the dry standardized products are preferable. In digipuratum, a dry digitalis extract was found free from the harmful digitonin and 85% of the bulky and inactive matter. The drug is standardized by means of the frog experiment so as to be equal in strength to the equivalent amount of potent leaves, this strength being uniform.

Digipuratum was employed extensively by the authors in the medical services of the Massachusetts General Hospital. Eight cases are quoted and tabulated, showing interesting features. The diuresis was efficient in all cases and a marked effect on the pulse-rate was usually present. One case was sent to the hospital in a moribund condition but reacted very quickly to the drug, so that compensation was re-established in a week. The digipuratum was usually given in the form of treatments of twelve tablets each, and while in some cases the first treatment gave little or no results, the second was always very efficient. Good results may often be obtained by combining the medication with venesection, the removal of fluid by tapping or by combining the digipuratum with other drugs, such as diuretin or apocynum.

Digipuratum has now been used in the Massachusetts General Hospital for over a year and more than one hundred and eighty cases of primary heart disease or secondary cardiac involvement have been treated with it. The effect on the urinary output has been very prompt in most instances. There was not a single case of vomiting or diarrhea; in fact, the vomiting of a number of cardiac cases at entrance was promptly stopped by digipuratum. Cumulative poisoning was never observed. One of the early patients, a boy of sixteen, was given one hundred and six tablets in six weeks; at no time was there any suggestion of digitalis poisoning. In one or two instances, the house officers were made uneasy by sudden drops of forty or more beats in the pulse-rate, but no disagreeable consequences followed in any case. It must be remembered, naturally, that

digipuratum is a digitalis preparation, but the tendency to produce poisoning is much diminished so that it is possible by means of this drug of reliable strength to push digitalis therapy in a manner hitherto unknown.

## REPORT OF MASSACHUSETTS COMMISSION FOR THE BLIND.

THE fourth annual report of the Massachusetts Commission for the Blind, for the year ending Nov. 30, 1910, describes particularly the efforts made by the commission towards the prevention of blindness, and the work done in extending and elaborating the means and methods of industrial training for the blind. There are now in operation three schools for such training, and seven workshops, where the blind may obtain regular employment in useful manufactures at an adequate wage. In an appendix, edited by Miss Lucy Wright, the general superintendent, are considered the measures already adopted, and those which it is desired to obtain, for the prevention of blindness from industrial accidents, from phlyctenular keratitis, and from ophthalmia neonatorum. The report emphasizes two of the most prominent aspects of modern charitable relief, — prevention and restoration to capacity for work.

## RECORD OF MORTALITY

## RECENT DEATHS.

DR. BOCTEAU, an early French experimenter with the Roentgen ray, died last week at Le Mans, France, it is said from cancer due to exposure to x-rays.

DR. AUGUSTUS G. ELIOT, who died in Rostock, Germany, on May 13, was born in 1820 at Woodstock, N. Y. After graduating from Yale, he studied medicine and began the practice of his profession in New York City. He was a founder of the New York Academy of Medicine, and for many years visiting physician to the Bellevue Hospital. He was twice married, and is survived by his widow, by one son, also a physician, and by two daughters.

DR. WILLIAM APPLETON RUST, who died on May 15 at Brookline, Mass., was born in Gorham, Me., on June 22, 1823. He received the degree of M.D. from the University of the City of New York in 1846, and settled in the practice of medicine at Paris, Me. Coming to Boston in 1866, he entered the wholesale drug business, in which he continued for a number of years. During this time, he served as a trustee of the Boston City Hospital, and was a member of the Boston School Board. He is survived by three daughters and by one son.

DR. WILLIAM ROBERT ANTHONY WILSON, who died on May 14 at Pittsfield, Mass., was born in Washington, Ill., on Jan. 28, 1870, the son of a physician. He received the degree of A.B. from Williams College in 1892, and that of M.D. from the New York College of Physicians and Surgeons in 1895. For a few years he practiced medicine at Peoria, Ill., but, being obliged to retire on account of sickness, devoted himself to travel and to literary work. He is known as the author of several popular novels. He is survived by his widow.

# INFLAMMATION OF LONG BONES, WITH SPECIAL REFERENCE TO EXCISION OF THE DIAPHYSIS.*

BY ROBERT G. LE CONTE, M.D., PHILADELPHIA.

*Mr. President and Gentlemen:* I desire to express to you my deep appreciation of the honor you have done me in asking me to read a paper here this evening. You may not know it, but the surgeons of Philadelphia have always had the warmest admiration for the surgeons and the surgery of Boston, and among the many notable contributions that have been made here, your development of surgery in acute inflammation of long bones has been of the greatest interest and assistance to me. In 1868, Dr. David W. Cheever was the first in this country to remove the shaft of the tibia and see the bone regenerate. Twenty years later, Heyward W. Cushing demonstrated the proper time for the removal of necrotic shafts by repeated microscopical examination of the periosteum, and seven years ago Edward H. Nichols published his classical article on acute infectious osteomyelitis. These contributions led to the choice of my subject for this evening, and I desire to review with you the work of a small group of surgeons, the staff and assistants of the Pennsylvania Hospital during the past decade, and to consider only the acute suppurative inflammations of the long bones of the extremities, namely, clavicle, humerus, radius, ulna, femur, tibia and fibula. I have excluded the jaw, ribs and bones of the hand and foot, as the uncertainty of the causes of their involvement rendered them unsatisfactory for our purposes in this paper, but whatever may be said of the bones under consideration applies to all long bones.

Acute inflammation of bone begins either in the periosteum or the medulla, the two structures from which bone receives its blood supply. The inflammatory process is similar to that occurring in the soft tissues, but, owing to the unyielding character of the part, the classical symptoms of redness, swelling and heat are not perceptible at first, and pain is out of all proportion to the other symptoms. Also, owing to its unyielding nature, the exudate interferes more promptly with the circulation, and local death or necrosis takes place much more rapidly, through shutting off the blood supply to a certain area of the bone.

Anatomically, inflammation of bone is divided into periostitis, osteitis and myelitis, but clinically we never see an acute osteitis without involvement of the periosteum or the medulla. Also, periostitis is always linked with inflammation of the adjacent cortex, and myelitis with inflammation of the surrounding bone, so the terms osteoperiostitis and osteomyelitis are clinically correct. When not interfered with surgically, an acute suppurative osteoperiostitis will speedily involve the medullary cavity, and likewise an osteomyelitis will sooner or later spread to the periosteum.

Let us consider these two conditions as one group and afterward separately. First, however, I desire to make a note of explanation for the small number of cases I bring before you. Our patients at the Pennsylvania Hospital are of many nationalities and frequently speak only the language of their country. In the absence of an interpreter, we are limited to a few words in obtaining the history, or perhaps only to the sign language, and, even with the interpreter, the ignorance of the patient or accompanying relative may be so great that we can get nothing much beyond the condition that is obviously present. Our histories, therefore, are sometimes too inadequate to be of value for study, and this has eliminated a number of cases which otherwise would have proved interesting.

The whole group consists of sixty cases.

### Analysis of Sixty Cases of Acute Inflammation of Bone.

| | | |
|---|---|---|
| *Etiology:* | | |
| Contusions, wounds and foreign bodies, | 38 | =63%. |
| Infection: | | |
| Staphylococcus pyogenes aureus, | 12 | |
| Syphilis, | 6 | |
| Measles, | 1 | |
| Scarlet fever, | 1 | |
| Typhoid, | 2 | |
| Unknown organisms, | 4 | |
| Unknown causes, | 4 | |
| | 68 | |
| More than one cause, | 8 | |
| | 60 | |

| *Age:* | | Per cent. |
|---|---|---|
| Before the fifth year, | 8 | =13 |
| Between fifth and thirtieth years, | 50 | =83 |
| After thirtieth year, | 2 | = 3½ |
| | 60 | |

| *Sex:* | | Per cent. |
|---|---|---|
| Male, | 54 | =90 |
| Female, | 6 | =10 |

| *Bone involved:* | | Per cent. |
|---|---|---|
| Tibia, | 47 | =73.5 |
| Fibula, | 6 | = 9.4 |
| Humerus, | 6 | = 9.4 |
| Femur, | 3 | = 4.7 |
| Ulna, | 1 | = 1.6 |
| Clavicle, | 1 | = 1.6 |
| | 64 | |
| More than one bone involved, | 4 | |
| | 60 | |

The frequency in males, the time of life when the disease is most commonly met with, and the bones involved, all point to the importance of an injury as the predisposing cause in the development of the disease. That in practically 75% of the cases the tibia was involved must be due to the large surface it presents covered by skin alone, and the frequency with which young males bump their shins.

* Read before the Boston Medical Library, Feb. 15, 1911.

The injury is usually of a slight or moderate grade, perhaps at times so trivial that it has made no impression on the patient's mind, or he has forgotten it a few moments after it has occurred.

In the more severe injuries, like simple fracture, acute inflammation of bone rarely occurs. I can recall but a single case, a child with bow legs, that was subjected to a double osteotomy and developed measles on the fifth or sixth day after operation. Both tibias were involved, suppurated, and later sequestra were formed.

In compound fractures, when osteomyelitis occurs, drainage of the wound usually limits the damage to a small area in the bone, or the injury and inflammation of the soft parts is so great as to determine a speedy amputation.

There are perhaps two explanations to be offered for the apparent frequency of bone inflammation after slight traumas. First, in the severe lesions so much blood and so many leucocytes are poured out at the seat of injury that the invading germs are at once held in check or destroyed. Second, when we consider the great number of slight traumas which every youth receives before he attains manhood, and contrast them with the few cases of acute inflammation of bone, it is not hard to believe that the ratio is thousands of slight injuries to one case of acute inflammation, and only scores of grave injuries to one that will develop osteomyelitis. The truth, therefore, may be that after grave injuries, acute inflammation of bone is much more frequent than after slight injuries. The real determining factor in all these cases is the circulation of pus cocci in the blood. If these are not present, an injury cannot produce a suppurating lesion in the bone unless the cocci gain access to the part through a wound.

It is not always easy clinically to differentiate osteoperiostitis from osteomyelitis, as a few days after the onset of the disease both conditions are generally present, and the decision of the nomenclature is more or less arbitrary, based on the previous history of the case. What does matter, however, is the appreciation of whether the disease is localized to the cortex and periosteum or has involved the medullary cavity. It is, therefore, difficult to consider these cases under two groups, when the starting point of the disease, whether central or on the surface of the bone, is the basis of classification. No matter where the starting point, each merges into the other after a more or less definite period of time has elapsed in the acute, virulent cases. This period we have computed to be somewhere in the neighborhood of seventy-two hours, a little less, perhaps, in very virulent infections, a little more in the mild infections.

ACUTE SUPPURATIVE OSTEOPERIOSTITIS.

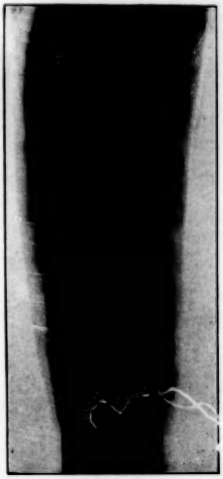
Number of cases, 41.
As the result of some form of trauma, 27 cases.
Infections without demonstrable injury, 14 cases.

| | Per cent. |
|---|---|
| Males, | 37=90 |
| Females, | 4=10 |

| *Bones involved:* | Per cent. |
|---|---|
| Tibia, | 32=70 |
| Fibula, | 5=11 |
| Humerus, | 5=11 |
| Femur, | 2= 4½ |
| Ulna, | 1= 2½ |
| | 45 |
| In which more than one bone was involved, | 4 |
| | 41 |

| *Age:* | |
|---|---|
| Before the fifth year, | 5 |
| After the thirtieth year, | 1 |
| Between the fifth and thirtieth years, | 35=85%. |

*Symptoms.* — Pain, local tenderness, swelling, redness, fluctuation, edema of the skin, with fever, and the constitutional symptoms of pus absorption, delirium, gastro-intestinal disturbances, etc. If the disease starts near a joint, there is frequently swelling of the joint, due to an increase of the synovial fluid. This is not of a septic nature and is rather a manifestation of the local hyperemia induced by the adjacent inflammation. When the subperiosteal pus is evacuated, the swelling of the joint subsides. The diagnosis is very easy in the superficial bones and more difficult in those well covered by muscle, but the x-ray at once clears up any doubt that may exist.



TERMINATION.

| | Per cent. |
|---|---|
| Resolution after superficial necrosis, | 14=34 |
| Resolution after local osteomyelitis, | 12=30 |
| Resolution after general osteomyelitis, | 10=24 |
| Deaths, | 5=12 |

Let us look at these terminations from the standpoint of *treatment*. Six cases are included in this group in syphilitics because they presented all the local and systemic symptoms of an acute osteoperiostitis and were probably due to a mixed infection. They were given iodides in addition to the local treatment, and all recovered after superficial necroses. Also 6 cases were operated upon within seventy-two hours from the onset of the disease. All were subjected to incision of the periosteum, disinfection and drainage. Five speedily recovered and one required a slight secondary operation for removal of superficial necrotic bone. In 7 cases shortly beyond the seventy-two hour period, the medullary cavity was opened and drained, 6 recovering without further operation, and 1 died. In 22 cases operated upon some time after the seventy-two hour period, in which the medullary cavity was not opened, all required the removal of more or less cortex, and in but 2 was the primary operation sufficient to insure healing. Four died and in the other 16 one or more subsequent operations were required, in 6 of which the entire shaft of the bone had to be excised. One remains in the hospital still unhealed. In 4 cases the medullary cavity was opened and found healthy and recovery ensued without medullary involvement. In the 5 deaths, staphylococcus pyogenes aureus was found in all,

No. 10. X-ray plate. Diffuse osteomyelitis tibia, sub acute.

No. 8. X-ray plate. Localized osteomyelitis lower end femur. (*a*) Rarefaction of oval area in the medulla. (*b*) Enlargement of the diameter of the bone.

No. 13. Photograph. Entire diaphysis of tibia removed at operation four weeks after onset of disease.

No. 14. X-ray plate. Partial excision of the tibia. (*a*) Regeneration of bone three months after resection.

No. 25. X-ray plate. Regenerating bone eight weeks after resection of the shaft of the tibia for an acute osteomyelitis of one month's duration.

No. 15. X-ray plate. Same patient as Nos. 12 and 14. (a) Developed scarlet fever after Plate 14 and bone fracture during removal to Municipal Hospital. Firm union after two months.

No. 26. X-ray plate. Regenerated tibia thirteen years after complete subperiosteal resection for acute osteomyelitis.

No. 27. Photograph of the same patient, No. 26.

No. 29. X-ray plate. One year after excision of the upper three fourths of the humerus. Regenerated bone.

and while we do not underestimate the virulence of this organism, it would seem that the treatment was the most important factor in their fatal termination. All were diagnosed as osteoperiostitis; all were seen more than seventy-two hours after the onset of the disease, and in only 1, ninety-six hours after the onset, was the medullary cavity opened.

*Acute osteomyelitis.* — There were 19 cases in which this diagnosis was made, and they represent for the most part a more advanced stage of the inflammatory process than the preceding group. Many of them probably began as an acute osteoperiostitis, and through delay in treatment reached the more severe stage.

*Etiology.* — Traumatic in origin, 11; and where cultures were taken, 7 proved to be staphylococcus pyogenes aureus.

| | | |
|---|---|---|
| *Age:* | | |
| Before the fifth year, | 2 | |
| After the thirtieth year, | 1 | |
| Between the fifth and thirtieth year, | 16 | =84% |
| *Sex:* | | |
| Male, | 17 | |
| Female, | 2 | |
| *Bones involved:* | | |
| Tibia, | 15 | =80% |
| Clavicle, | 1 | |
| Humerus, | 1 | |
| Femur, | 1 | |
| Fibula, | 1 | |

The cases in this group presented themselves a week or more after the onset of symptoms. Three cases are included which properly do not belong here, as they were evidently chronic osteomyelitis. But as they came during an acute exacerbation, with systemic symptoms and foul discharge of pus, and in each the shaft of the tibia was excised, we have included them for the purposes of study.

*Symptoms.* — The symptoms were practically classical, as furnished in every textbook. Prodromes for the most part are slight or absent, although the patient may complain of exhaustion or malaise. This is quickly followed by pain, which is often accompanied by an introductory chill with high fever. The pain at first is vague, but soon focuses in the particular bone involved, and as a rule speedily becomes agonizing, and as its intensity increases, the tenderness increases and becomes exquisite. Redness and swelling soon appear in the virulent cases, and with it there is commonly a swelling of the neighboring joint. The involvement of the joint is primarily never purulent and it becomes so later as the result of delayed treatment, by extension from the primary suppurating focus. When edema, fluctuation of a periosteal abscess or loosening of the shaft from epiphysis occurs, any one of these signs is pathognomonic. Sometimes the disease is so rapid in its development, through the virulence of the infecting organism, that septicemia or pyemia shortly develops, and other bones may become involved. There is a high leucocytosis, averaging 18–20,000.

*Diagnosis.* — The disease for which this condition is most commonly mistaken is acute rheumatism. In acute rheumatism the swelling of the joint is coincident with the pain, and usually proportionate to the pain, and in but rare instances does the disease assume a septic type. The lesions of rheumatism are usually multiple; those of bone infection for the most part single. In rheumatism the pain starts in the joint; in acute osteomyelitis somewhere along the shaft of the bone. In acute osteomyelitis the disease assumes from the very onset a seriousness and gravity which is seldom if ever approached by acute inflammatory rheumatism. Rheumatism is never followed by suppuration, but valvular lesions of the heart commonly appear early in the disease. The importance of the diagnosis between these two conditions is at once apparent, for if adequate surgical measures are not promptly resorted to in acute osteomyelitis, the mortality from the disease is high, the destruction of bone great and the ultimate usefulness of the limb seriously compromised.

When all other signs fail, it will be safer for the patient if we consider every case of mon-articular swelling in children and young adults, with sudden onset and marked constitutional symptoms, as one of acute osteomyelitis until this diagnosis is confirmed or disproved by the x-ray. The diagnosis can be made much earlier by the x-ray in bones that are well covered by muscle.

In the inflammatory process of bone we find one of two pathological conditions taking place after the acute symptoms subside:

(1) An inflammatory process analogous to the formation of an abscess in the soft tissues, with an attempt by nature to isolate and cast off the dead tissue in the form of sequestra.

(2) A diffuse inflammation of the bone analogous to a cellulitis in the soft tissues, in which the greater part or the whole shaft of the bone is involved.

As the result of prompt and radical surgical intervention and a normal resistance of the individual to infection, localization of the inflammation may take place. If the process appears quiescent, it should not be disturbed for one or two months until the sequestrum may be felt free within the cavity. The cavity should be freely opened then, the sequestrum removed, together with the granulations lining the wall, and the cavity swabbed with pure carbolic acid and allowed to fill with granulations. If, however, the inflammatory process does not limit itself, involving more and more of the bone, a radical removal of the diseased tissue is indicated. In the above group of cases the mistake of not opening the medullary cavity at the primary operation was made in three, one of which died, and in the other two, sequestra were formed.

It is perhaps best that we transfer to this group 10 cases which were quoted under osteoperiostitis, and the 5 deaths, as in all of the 15 cases through delay or inefficient surgical treatment a diffuse osteomyelitis was present. These 15, when added to the 19 cases under this heading, make a group

of 34 for study. The 6 deaths, therefore, represent a mortality of 17.5%. In 16 cases in which incision of the periosteum, partial excision of the bone (i. e., any removal less than the complete circumference of the shaft), sequestrotomy or erasion were performed, 8 required one or more subsequent operations, 7 were unhealed, having a sinus remaining when they were discharged from the hospital, and only one healed after the primary operation. Twelve cases required extensive subperiosteal resection or complete excision of the shaft of the bone. Three of these total excisions were attempted after the disease had existed for over a year, and in 2 there was no regeneration of bone. The other case left the hospital six weeks after operation and it has been impossible to trace him and find out the ultimate result. None of the other 9 cases required further operative treatment, and the average period for complete healing and regeneration of bone was six months; the minimum time, two months; the maximum, one year.

Our practice in extensive subperiosteal resection or complete excision of the shaft differs somewhat in two particulars from the method advised by Nichols, namely, in the manner of treating the periosteum after the excision and in point of time when the excision should be done.

Nichols advises the disinfection of the periosteum, the sewing together of its cut edges, making a tube of it, and the closure of the soft parts over it, with a wick for drainage at each end of the incision. Our technic started with my first case, a boy of ten, in February, 1898, six years before Nichols' article appeared, and some time before Cushing's observations were printed, so that we did not have the advantage of their scientific work. In this case the entire shaft of the tibia was removed, the periosteum disinfected and the whole cavity of the wound packed with gauze, not a suture being used. The lower epiphysis was involved and required a subsequent second opening and curettage. The tibia was reproduced, practically like its fellow, and developed thereafter normally with the other limb, except for some shortening. This method having proved satisfactory, we continued to use it in our subsequent cases until Nichols' article appeared. Then we tried a case by his method, but whether through some fault of technic or other error, the case did not do well, suppuration was free, the chromicized catgut sutures gave way, the whole wound reopened and had to be packed, and eventually the bone was regenerated. Whatever our fault may have been, we do not know, so that we have gone back to packing without suture.

As to the time when the excision should be made. We agree with Nichols that the periosteum gives evidence of its maximum power of reproduction after the acute symptoms have subsided, somewhere toward the end of the second month, or beginning of the third month in the presence of a dead shaft, but we go a step farther and believe that it will do this at a very much earlier period if the necrotic tissue is removed. In any tissue where healing or regeneration of that tissue takes place in the presence of pus, we have a very considerable over-production, because a portion of the new material produced is destroyed by the infectious material present. In the presence, therefore, of a dead shaft or one that is bathing the reproductive surface of the periosteum with pus, the effort of the periosteum to reproduce bone is being constantly combated by the septic material present, and quite a portion of the material which it is reproducing is destroyed by the organisms. Therefore, the sooner the infective material is removed, the quicker will be the healing, which in this instance means the reproduction of the bone, and the less will be the task imposed upon the periosteum. Our aim, therefore, should be to get an aseptic periosteum at the earliest possible moment, no matter how little nor how much suppurating bone is removed at the primary operation.

Let us look at this question in another way. We get a case of acute inflammation of bone at the beginning of the fourth day. An opening is made into the medullary cavity as broad as a little finger and, say, two inches long. The case recovers without further operation because only a very small amount of bone has become involved. The drainage is adequate to prevent a further extension of the infection and the periosteum reproduces the defect of the removed bone. Take a case on the eighth or tenth day. Here we open a subperiosteal abscess, find the bone beneath soft, reddish and perhaps exuding pus. The medullary cavity is opened broad as a little finger, and this excision of bone is extended up and down the shaft until we reach healthy bone above and below and expose healthy marrow. For a time the acute symptoms disappear and the case looks convalescent, then sepsis reappears and another operation is necessary. Why? Because at the primary operation we were satisfied with adequately draining the medullary cavity as far as it was involved, and paid no attention to the inflammation that existed in the cortex. When the infection starts centrally and we attack a bone on its most superficial surface and find it infiltrated with pus, there is no reason why the opposite side should not be in precisely the same condition. Had the incision, therefore, extended around the circumference of the bone until healthy structure was encountered, the primary operation would be sufficient and the periosteum would fill in the defect. If, as we keep on removing the cortex of the bone, we find the whole circumference involved, why not resect the bone until we encounter healthy structure above and below? The periosteum just as surely will fill in the defect. In one case, a boy of ten, operated upon the tenth day after injury, and the fifth day after the initial chill, all of the lower third of the tibia was removed except a narrow strip one-eighth by three-fourths inch, which strip appeared healthy. The bone was reformed and the case completely healed in less than three months without subsequent operation. Two cases were operated upon at the end of four weeks,

the whole shaft being involved and removed, and healing took place in thirty-seven weeks. In one case operated upon at the end of the fourth week, the whole shaft being removed, there was partial regeneration at the end of thirty-six weeks, and complete when the child was again seen at the end of a year. Two cases were operated upon at the end of the fifth week, in which three fifths of the shaft was removed and the average period of healing was thirty-six weeks. One case of six weeks' duration, where the whole shaft was removed, was healed in thirty-six weeks. In these six cases, all of them done early, before the periosteum showed any sign of involucrum formation, the defect in the bone was completely regenerated and they required no subsequent operation after the shaft was removed. Also in all cases where more or less bone was excised short of a resection, the defect was promptly filled by periosteum. Many of these cases were treated with extension to combat muscular retraction and consequent shortening of the bone. It would, therefore, seem that there is no period too early in the disease for the periosteum to regenerate the defect in the bone removed. In the three other cases of regeneration, the operation was nine weeks, seventeen weeks and twenty-eight weeks after the onset of the disease, the latter, a child of two in which the clavicle was removed and healing was complete at the end of twelve weeks. Theoretically, it would seem probable that the younger the child, the more quickly regeneration would take place, but a contrasting of the ages of our patients with the duration of time needed for complete regeneration is totally unprofitable, for the conditions at the time of operation were so variable that no deductions of value can be drawn. In general, though, it would seem the older the patient, the larger the bone, the longer the time of regeneration.

If there is no time too early, there comes a time when it is too late for the periosteum to reproduce a shaft. It would seem that its energy at reproduction is expended, either from exhaustion in its effort at combating the disease, or its accomplishment of an involucrum so firmly adherent to the sequestrum that involucrum and shaft must be removed together. Under these conditions bone will seldom be regenerated, as instanced in 2 of the above cases, 1 a year and the other twelve years after the onset of the disease. The limit of time when the periosteum will cease to reproduce seems variable, but in the absence of an involucrum its power of regeneration seems to decrease progressively after six months, and where an involucrum is present and must be removed with the shaft of the bone, the power of reproduction was totally wanting in our cases.

The term "completely healed" means not only that all wounds and sinuses were closed, but also that the patient had the use of the limb, in the majority of the cases without any form of apparatus; in a few a light brace was still worn.

In reviewing these 60 cases as a whole, I think we can fairly draw the following conclusions:

(1) The mortality and extent of the necrosis following acute inflammation of bone depends not only upon the promptness of surgical interference, but also upon its thoroughness.

(2) That suppuration beneath the periosteum does not exclude an infection of the medulla, the presumption being that after three days the medullary cavity is also involved.

(3) That within seventy-two hours of the onset of the disease osteoperiostitis is localized usually in the cortex of the bone, and incision, disinfection and drainage are sufficient to bring about a cure. If there is no marked diminution of the symptoms in twenty-four hours after incision and drainage, the medullary cavity should be opened.

(4) When the medullary cavity is opened and found healthy, the dangers from infecting it are slight.

(5) In the majority of our cases osteomyelitis was due to a neglected osteoperiostitis.

(6) In operations after the third day, where systemic symptoms are pronounced, the medullary cavity should always be opened and the opening should be sufficiently long to expose healthy marrow, and sufficiently broad and long to expose healthy bone.

(7) Our mortality of 10% was directly due to delay in operation, and to inefficient surgery at the primary operation. In 5 of these cases I am sorry to say that the surgery was at fault, and had a radical operation been done I believe that all would have recovered. In the sixth case the delay in operation was perhaps more responsible than the surgery for its fatal termination. It is but fair to say that in collecting these 60 cases, perhaps 40 more were rejected for various reasons, none of whom died, so a mortality of 6% is nearer the truth.

Lastly, our surgery was bad, very bad in a number of cases, and the tendency to wait after giving drainage, to my mind, was not sound. I firmly believe that the attempt should be made in the acute stage to remove at the primary operation all bone that is diseased. We know that the periosteum in the acute stage of the disease will reproduce all bony defects, and delay means a greater number of operations, a greater destruction of bone, a greater likelihood of epiphyseal inflammation, a longer convalescence and perhaps a higher mortality. Twenty years ago we were satisfied in appendicitis with opening and draining a large abscess. To-day we say that some one has blundered when we receive a case in the abscess stage. I feel that the necessity of resecting twelve shafts in 60 cases, namely, 20%, is an error of this same sort, for if efficient surgery had been done early, the condition would not have arisen for such an extensive operation. As Nichols has pointed out, the resection of a whole shaft is but little less shocking to the patient than an amputation, and the operation has a very definite danger from hemorrhage, and in a few cases, on account of the hemorrhage, it has had to be done in two stages. My plea, therefore, is for

an early diagnosis, and, to continue the simile of the appendix, to abolish the Ochsner treatment of delay and to treat acute inflammation of bones as we would a similar inflammation in the soft tissues, as instanced in a carbuncle, by radical excisions at the primary operation.

## THE ACTION OF SALVARSAN UPON THE WASSERMANN REACTION.*

BY HOWARD FOX, M.D., NEW YORK.

DURING the past year there has certainly been an astonishing amount of investigation upon the clinical action of salvarsan. As a result we now have a fairly good idea as to what the new remedy can or cannot accomplish from a clinical standpoint. We know that the drug produces brilliant symptomatic results, and we also know that relapses occur with more or less frequency. From the proportion of such relapses we of course can form an opinion as to the permanence of the action of salvarsan in syphilis. To judge, however, of its effects in the latent stages of the disease it is necessary to depend upon successive Wassermann tests, carried out over a considerable period of time.

Although the literature of salvarsan is already very voluminous, it contains as yet comparatively few reports of value relating to the Wassermann reaction. The discrepancies in the various reports are very great and are due largely to the difference in the number and kind of injection and to the stage of the disease in which the injections were given. The percentage of negative reactions obtained by different observers vary from over 90% to 5% or even less, as shown in the following reports:

In 52 cases that were serologically followed for fifty days or more, Schreiber and Hoppe [1] found that the Wassermann reaction changed from a positive to a negative in 92.3%. In most of the cases the reaction became negative at the end of fourteen days. Neisser and Kuznitzky [2] found that the reaction changed in 44% of one hundred cases examined, occurring generally twenty to thirty days after injection. Of 27 cases reported by Isaac,[3] only one became negative. Nearly all remained positive in spite of the disappearance of clinical symptoms. In 27 cases of Braendle and Clingestein,[4] only one changed from positive to negative. Lange,[5] who examined Wechselmann's cases, reports that 57% of 268 cases became negative. In the strongly positive cases, the change occurred on an average from four to five weeks, while in the weak cases it took only eight days. Stern [6] gives 50% of negative reactions occurring in four to six weeks. MacRae,[7] who examined Fordyce's cases, obtained seven negative reactions in 54 cases. In 9 cases the reaction was modified. In 42 cases (males) reported by Lesser,[8] 15 became negative on an average of thirty-seven days. In 24 cases (females), only 2 became negative. Géronne [9] examined 193 cases and found that less than 50% became negative. Plaut [10] found two negative reactions in 41 cases after six to eight weeks. Scholtz, Salzberger and Beck [11] report twenty-one negative reactions in 80 cases. Pick [12] found that the change from positive to negative took place in the majority of his cases (138) in four weeks, the shortest time being twelve days and the longest seven weeks. In 27 cases of Loeb,[13] 12 became negative, of which 2 again became positive. Goldenberg and Kaliski [14] found that only 3 out of 39 cases became negative, of which 2 again became positive. Freund [15] obtained fourteen negative reactions in 43 cases. From an experience of 83 cases treated by the intravenous method, Favento [16] reports that the reaction remained positive in the majority of cases, although of a lessened intensity. In 54 cases followed by Von Marschalko,[17] a complete negative reaction was only obtained a few times. Swift [18] reports the result of 42 cases, some of whom had been treated by the intramuscular and others by the intravenous method. His results show an advantage on the side of the intramuscular method. He states (personal communication) that since the time of writing the disparity in favor of the intramuscular injection has lessened. In a splendid work involving great labor and care, Noguchi [19] and his assistant, Brenfonbrenner, examined quantitatively 102 cases at frequent intervals. The reaction became negative in 33.7% of their total cases. They found the best results to have followed the intravenous method of injection.

From the observations above quoted it can be seen how difficult it is at the present time to form a definite opinion as to the action of salvarsan upon the Wassermann reaction. In the majority of the reports the results were obtained by a single injection only of the drug, and mostly by the subcutaneous or intramuscular methods. In general the results of one injection cannot be said to be very satisfactory from the serological standpoint. According to Spiethoff,[20] the action on the Wassermann reaction of a single large or moderate dose of salvarsan given in any stage of syphilis by either subcutaneous or intramuscular methods is "entirely unsatisfactory." He obtained the best results by the Iversen method of giving an intravenous followed in a few days by an intramuscular injection. In addition to this he gave a second intravenous injection at the end of four weeks. The superiority of the Iversen method was shown not only clinically but also serologically, as during an observation period of four months, no relapses occurred.

In a valuable communication, Gutmann [21] describes the results of triple intravenous injections. In 27 cases he was able to follow the Wassermann reaction and found that in all except 2 cases it became entirely negative, even after the second injection. In 14 of these it changed in from two to six weeks. In 9 cases the reaction did not become negative until the third injection had been given. The two failures occurred in cases of late syphilis.

According to Fritz Lesser [22] the best results upon the Wassermann reaction are obtained by giving repeated intramuscular injections of one decigram. He finds that in the majority of cases the reaction becomes negative after the sixth injection. He does not state unfortunately just what percentage of his cases became negative, nor how frequently it was necessary to exceed six doses.

The action of salvarsan upon the Wassermann reaction is probably due to a lessening in the

* Read before the New York State Medical Society, April 18, 1911, in a symposium on Salvarsan.

amount of antibodies. That it is not due to any chemical change by which the serum is rendered more hemolytic has been shown by the experiments of Schwartz and Flemming.[23] The action is in general analogous to that of mercury. In a certain proportion of cases a positive reaction changes to a negative, generally about the sixth week, although the change may take place as early as the fourth day (Schrieber and Hoppe, Noguchi). In some of these cases the negative reaction later becomes positive. At times the positive reaction remains unchanged or for some

unknown reason can even become more strongly positive (Lange, Von Marchalko, Freund). The negative reaction may take place by a regular and gradual decrease in strength, or there may be at times marked oscillations, the reaction being one week positive and the next negative or vice versa. According to Herxheimer, such oscillations may be due to differences in absorption of the drug. In the table given by Zieler [26] such changes are shown in a marked degree. Finally the reaction may become entirely negative in the presence of a florid exanthem (Weiler [25]) and as in Case 24 of my table.

The action on the Wassermann reaction in the different stages of the disease is closely analogous to that of mercury. According to Heuck and Jaffé [28] the change from positive to negative is quickest in the primary stage, is slower in secondary and malignant syphilis and still slower in the tertiary stage and in syphilis hereditaria tarda.

It has been found by a number of observers (Géronne, Reiss and Krzysztalowicz [27]) that equally good serological results can be obtained with smaller as with the larger doses usually employed. The good results of Lesser with intramuscular injections of small doses have already been mentioned. Isaac [28] also states that when using large doses for intramuscular injections he obtained negative reactions rarely or only after long periods of time. When using small doses of one decigram, the reaction became negative in most cases after the sixth injection.

The effect upon the Wassermann reaction is very unfavorable compared to its effect upon the clinical symptoms. It is a common experience to see strong positive reactions continue for considerable periods of time in cases in which the clinical symptoms had disappeared with surprising rapidity.

The Wassermann reaction is finally not only of value in determining the permanence of the action of any antisyphilitic remedy, but is also of great importance in deciding whether the disease can be aborted by early treatment. Finger [29] reports favorable results of early treatment in 5 cases of primary syphilis. The cases were negative before treatment. The reaction in each case was negative before treatment and remained so for periods of twelve weeks to six months, during which time no secondary manifestations had appeared. Similar results are reported by other observers.

My personal experience is derived from about ninety injections of salvarsan given in conjunction with my colleague, Dr. William B. Trimble. Most of the work has been done in the service of my father, Dr. George Henry Fox, at the New York Skin and Cancer Hospital. With several exceptions I have only included in my table the cases in which the blood examinations were made during a period of five weeks or more. In over half of the cases the blood was tested at the end of two to six months. In all of the 34 cases in my table, the Wassermann reaction was positive before the injection. In 13 of the cases it became negative after treatment, at intervals varying from three to eleven weeks. Of these cases, 8 had been treated with a single intramuscular injection, 4 with a single intravenous injection, and one by a combination of the two methods. While this would seem to show an advantage on the side of the intramuscular method of injection, the number of cases is too small from which to draw any general conclusions. In a later communication I hope to have a more complete material and to give a detailed comparison of the clinical and serological results that have been obtained in our cases.

## CONCLUSIONS.

1. It is difficult at the present time to draw general conclusion owing to the great discrepancies in the results of various observers.

2. These discrepancies are partly due to the different methods of injection and to the different stage of the disease in which the injections were given.

3. The results of a single injection given by either the intravenous or intramuscular methods are as a rule rather unsatisfactory from the serological standpoint.

4. Repeated injections seem to have given better results and offer a more hopeful outlook for the future.

5. The action of salvarsan upon the Wassermann reaction is in general analogous to that of mercury.

6. The effect upon the Wassermann reaction is much less favorable than upon the clinical manifestations of syphilis.

## THE EARLY DIAGNOSIS OF PULMONARY TUBERCULOSIS FROM THE STANDPOINT OF PHYSICAL AND FLUOROSCOPIC EXAMINATIONS.

BY JAMES A. HONEIJ, M.D.,

*X-Ray Department, Boston City Hospital.*

THE present paper, on the question of early diagnosis of tuberculosis, is the result of my personal observations on some hundreds of patients with positive and suspected signs of tuberculosis examined at the Boston Comsumptives' Hospital and the Boston City Hospital. I have closely followed the many suggestive symptoms of those patients who either from their family history or from their past or present history excited suspicion of some trouble in the lungs. I have unfortunately not been able to follow closely patients with very obscure symptoms and who are likely to develop more positive symptoms of tuberculosis later on. Many patients showed an utter disregard of their condition, which in some cases was serious. However, I fortunately met with success with some, all of whom were children, whose parents showed sufficient appreciation to make their visits at periodic times for examination and re-examination. And it is from these cases that I have obtained the most satisfactory results from my work. This paper may be of some especial interest from the fact that the diagnosis was at no time based on physical findings alone, but in all cases was borne out or modified by fluoroscopic examinations. The older methods and ideas concerning tuberculosis, which dealt mainly with the advanced class of cases — instructive undoubtedly to the student, but of no benefit to the patient —must necessarily give way to a more modern method of diagnosis by which the disease is detected in the early curable stage. The diagnosis of a case in which many of the well-known symptoms are clearly present (Cases Nos. 2 and 5) is not a difficult matter, but in the cases of those who have come for totally different reasons than for apparent tuberculosis, diagnosis of the chest is increasingly difficult. Very often patients visit the clinic because they fear that from association with tuberculous patients they have contracted the disease. Here is where care has to be taken in attempting either to detect the very earliest signs of the disease or to be willing to presume that any questionable change in percussion or auscultation means the gradual onset of tuberculosis. Patients as a rule did not care to be told that they were suffering from lung trouble, and most showed a surprising amount of sensitiveness and fear if told of the changes that were suspected in the lungs. Again, a great many of the earliest changes in inspiration or expiration or even in percussion may prove to be nothing but transitory bronchial trouble or a normal physiological condition of that patient (see Case No. 3). Again, changes may have occurred in the lungs and on examination may be obscured by other conditions present. I have seen a number of patients in whom distinct râles were obtained over apical areas of the lung and which proved to be a temporary affair. In many instances noticeable changes were found in percussing the lungs, and these changes, thought to be due to tuberculosis, often associated with some change in respiration, upon fluoroscopic examination proved to be illusory (see Case No. 3).

Extremes were often met with, for in two particular instances the patients gave an undoubted hostory of many hemorrhages. In the one case, the patient visited most of the hospitals and sanatoria, was treated for various periods of time without any positive diagnosis other than that based on the repeated hemorrhages. Upon physical examination very slight changes were found, and these only after several examinations. Even on x-ray examination nothing very positive could be obtained. The second patient was found in an advanced stage, which had evidently been progressing for twenty-six years (Case No. 2) and at no time was she incapacitated by her condition. On the other hand, patients with a definite history of night sweats, temperature, cough and expectoration on physical examination showed so small a change that the diagnosis was deferred, and only upon x-ray and fluoroscopic examinations did a positive diagnosis result (Case No. 4). In children especially do we find variations from the normal, and still so indefinite as to make the diagnosis of tuberculosis impossible. Surprisingly often we find that children whose parents are tuberculous are not brought in to be examined until they manifest a continual cough.

In a particular case I have in mind, the patient, a woman of forty years, had been suffering some time from tuberculosis. There were several children in the family, and although she was treated and warned as to her condition, and the danger of spreading the disease, she continued living in a small room and sleeping with the windows closed. No care or precaution was taken to have the children in different rooms. Some months later, upon very careful inquiry as to the condition of the children, it was found that one child had been coughing for two years and another for six months. The physical examination in both children showed tuberculosis.

Contrary to what I had expected, most of the patients examined were by birth American. The majority of the patients' (excepting children) occupations was "home"; a number had other indoor occupations, such as tailors, dressmakers, pressers, etc. These findings may, of course, be entirely due

to the vicinity of the hospital and the class of patients, or to the fact that the poorer classes are being treated by the tuberculosis clinics and societies.

By far the most interesting fact I obtained was the close connection or association of tuberculosis with other diseases. In children pneumonia seemed to be more than a predisposition to tuberculosis and pointed to a closer union between the two diseases, but if this is the conclusion in pneumonia, then pleurisy can be said to be a form of tuberculosis, for in the majority of cases patients had had pleurisy some time previously. So also in other forms of chest trouble, as bronchitis, influenza and pertussis. Arthritis in some form is believed to have some association with tuberculosis, but the number of cases was not large enough to draw any conclusions from them. However, in seven cases out of a hundred there was or had been arthritic trouble.

As to the symptoms or causes that compel patients to visit the clinic, they are numerous. The first is undoubtedly a cough which the patient may have had for an indefinite time. Surprisingly seldom, however, does the patient complain of cough with expectoration. Pain is a common symptom — pain in the shoulders or chest, front or back. Loss of weight with pallor and languor is also often a cause. Undoubtedly a good history of the symptoms of the patient will carry conviction to a diagnosis that is made upon questionable signs.

Family history (such as in Case No. 1), even if there happened to be no sign of tuberculosis, would naturally force extra care and examination of the patient. The routine examination of the patient, apart from his history, was the same in every case, so as to assure a uniform comparison of the cases. The physical development was noted, breathing both normal and deep, with and without chest expansion. The fossæ above and below the clavicles were compared, and often some intimation of trouble in the apices was shown.

The method of examining the patient was to seat him in a good light and then stand behind and look over and across the top of the shoulders, then upon deep breathing an idea was obtained as to the amount of expansion each apex had. The skin was felt and a note made as to whether it was dry, moist, soft or thick. A growth of hair on the back and arms was evident in a few cases which showed other typical illustrations of tuberculosis. The length of the eyelashes, the color in the cheeks, the brilliancy of the eye and many of the minor details were, as a matter of routine, taken note of.

*Fremitus.* — Tactile fremitus, whether increased or diminished, harsh or faint, has given the first inkling of trouble, next to percussion.

*Percussion* at all times must necessarily vary, and often becomes a question among physicians. Light percussion is what I practiced, and from which I obtained the best results. Dullness or resonance or even a normal sound may be obtained, but varying in the pitch over both lungs. Here, however, especially in children, the change may be purely physiological. In advanced cases, there can be no question, but it is to be borne in mind that we are dealing only with the early changes in tuberculosis.

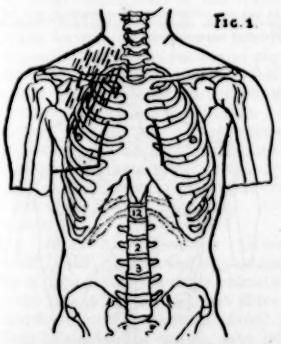
In one case examined, the patient had pleurisy and three weeks later came to be examined. On the left side in front from the fifth rib downwards, and in the back on the same side from the mid-scapular downwards, there was dullness to flatness; the left apex, however, on account of the comparison, seemed perfectly resonant and of good quality, and in the right apex, a still better percussion note was obtained. On auscultation and further examination nothing very definite was obtained, only a suspicion of small trouble in the left apex. On fluoroscopic examination there was shown quite an advanced degree of density in the left apex, and a smaller process in the right apex. I quote this case as a proof of how easy it is to be led astray in comparing positive dullness and flatness to a lesser note elsewhere in the chest. And in examining many dozens of patients it is an easy matter to slur over those cases in which the grades of sounds are finely differentiated.

*Auscultation.* — First the normal breathing, the length of inspiration compared to expiration, the harshness or pitch of inspiration compared perhaps when the patient is breathing deeply, and a note made of any extraneous sounds that occur during breathing. If râles were present, then a note was made whether they were crackling, bubbling, dry or moist, coarse or fine, and whether persistent or transient. In auscultation we often obtain the very first change which is found in tuberculosis, and slight changes are of sufficient importance to draw extra attention to them. In children, especially, there is difficulty in diagnosing the numerous grades of sounds obtained during inspiration and expiration; in a number of cases examined, the very opposite results were obtained by fluoroscopic examination.

The weight, temperature and pulse were taken at each visit of the patient. The temperature is a good index of the patient's condition, and very often some idea is obtained of the amount of work or exertion undergone during the week. The pulse in most of the cases has averaged from 82 to 86 beats per minute. In early cases no such pulse or temperature is constantly obtained, although in both these points of observation there was sufficient increase noticed. The weight is of more importance after your diagnosis has been made, unless the patient's history gives loss of weight within a very short space of time, and then usually the case is more likely to be classed as an advanced process than as one of early tuberculosis. The shape of the chest has not given any information in regards to an early leaning toward tuberculosis. But chest expansion on the other hand certainly seems to be a point well to bear in mind; in the majority of positive cases, the expansion in adults hardly ever exceeded 4 cm. and averaged about $2\frac{1}{2}$ to $3\frac{1}{2}$ cm.

*Litten's* phenomenon appears to be of exceedingly small value. In only a very few cases was it obtained in such a way that a positive

measurement could be taken of the excursion of the diaphragm, and, on the other hand when obtained, never once did it correspond with the tracing obtained by fluoroscopic examination. In cases where one or the other side of the chest had a lesser degree of excursion, and when actual measurement was taken, never did it correspond with the fluoroscopic examination. And, more than that, very often there was actually a reversed order of things. The side which on physical examination showed the smallest amount of excursion had, on fluoroscopic examination, the greatest excursion. It is natural, then, to have but little faith in such an inaccurate phenomenon, especially when it is of such doubtful value. In one patient the excursion of the diaphragm on physical examination was 1¾ inches on the right and indefinite on the left side. This proved by the fluoroscope to be 2 inches on the left, and a fraction over 2 inches on the right. In another case a woman with Litten's sign seen exceptionally well, and which was thought to be a normal excursion for the individual, equal on both sides, showed by fluoroscope to be unequal and fully an inch more on either side. I quote Litten's phenomenon here because it was thought at first to be of value in the diagnosis of tuberculosis. *Excursion* at the bases proved of value in advanced cases only; usually, however, very little difference was obtained on actual measurement.



The cases I have quoted and those I present with this paper I have chosen more with the idea of comparison than to show typical cases illustrating changes found in early tuberculosis.

### Case No. 1.

Woman, age fifty-six, widow, housework, born at Cape Breton.

*Family history.* — Grandmother died of tuberculosis.

Fig. 1.

*Front and Back.* On right side, as shown by shading, slight dullness to fourth rib in front and to mid-scapular behind.
Tactile and vocal fremitus increased.
Inspiration rough, expiration slightly loud, but not definite broncho-vesicular character.
No râles.

Mother had tuberculosis. Son died at twenty-three years of tuberculosis, a year ago.

*Present illness.* — Nov. 14, 1906, complaint of general pains, and frequent micturition. Exertion leaves her weak. Headache, nausea. Some edema of ankles with pain. All else negative.

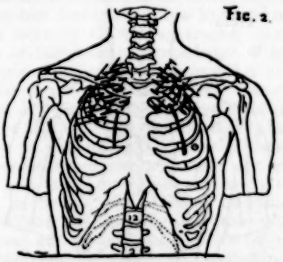
*Urine examination.* — Acid; specific gravity 1005.

*Weight.* — 125 lb.

Physical examination negative.

On Dec. 12, this history was obtained. Thirty-two years ago patient had severe attack of pleurisy on both sides; since then has been troubled with indigestion and severe pain over stomach. Pains gradually became worse. Twenty-two years ago pains very bad; a year afterwards had fainting spell, vomited "several quarts"? of blood, at first clots, then clear blood; few days later again vomited a great quantity of blood. Very sick for three months. Fairly well since then. Last winter pains came back, mostly in legs. Severe cough developed, with loss of appetite and weight. Some night sweats. Sputum thick, pus like, small in amount. During summer gained in weight and strength.

Physical examination of chest shows slight prominence of upper end of sternum. Both sides of chest expand equally.



*Lungs.* — Negative save for slight dullness and increased tactile fremitus at apex right side front and back. Further lung examination gave the following results, which are best described by a diagram.

*Fluoroscope examination* shows both lungs to be very obscure. Ribs not seen.

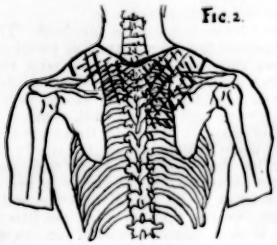
### Case No. 2.

Woman, age thirty-eight, married, dressmaker, born in Sweden.

Fig. 2.

*Front.* Apical outlines diminished. Dullness as shown by shading on diagram. Breathing: On right, over dull area, bronchial; with coarse and fine crackling râles on left, broncho-vesicular breathing with râles as on right.
Fremitus increased at right apex.

*Family history.* — Father and mother had tuberculosis. Sister has tuberculosis. Mother had chronic cough and many hemorrhages.



*Past history.* — Measles and scarlet fever as a child. Patient at twelve years of age treated in Sweden for tuberculosis. Coughed a great deal, expectoration mixed with blood. At seventeen years had anemia. At twenty years had attack of coughing with several hemorrhages, very sick. At twenty-eight years another attack accompanied by severe pain in chest and back, since then always raised good deal of phlegm. At thirty-two years had fourth attack with high temperature and night sweats. Arrived in America four years ago; stronger since, but has lost weight. One child born nineteen months ago, died two weeks ago of pneumonia. Has been troubled lately with small cough with some expectoration. Fever with night sweats.

*Present illness.* — Complains of cough and night sweats with hemoptysis. Loss of weight.

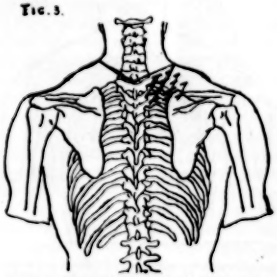
*Physical examination.* — Best illustrated by diagram. Temperature, 99.6.

*Fluoroscope examination.* — Shows a definite diffuse tubercular process.

FIG. 2.

*Back.* Apical outlines diminished.
Dullness as shown by shading on diagram. Breathing over dull area is of a bronchial type with many coarse and fine crackling râles, more marked in mid-scapular region.
Fremitus is increased.

CASE NO. 3.



Male, age five and one-half years, attending school, born in Boston.

*Family history.* — Mother treated for tuberculosis.

*Past history.* — Has never been strong. A year ago had adenoids and tonsils removed. Pneumonia shortly after.

*Present illness* (Nov. 26, 1907). — Cough past nine weeks. Appetite poor. Constipated, bad breath.

FIG. 3.

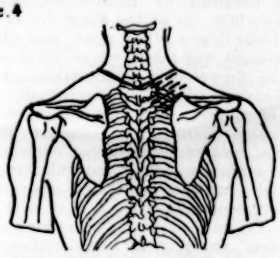
*Apical outlines* (back) on right possibly slightly diminished. Dullness shown by shading. Breathing is broncho-vesicular. Fremitus is increased at both apices, but very definite on right.

(Dec. 12, 1907.) All last week very sick. Foul stools. High fever. In bed most of the time. Cough has increased; some days cough steadily. Some vomiting. No expectoration. Sweats every night profusely.

*Physical examination.* — Best shown by diagram. Temperature, 99.6; later, 99.0.

*Fluoroscope examination.* — Both lungs seem clear. Diaphragm possibly lower than normal. About the level of the third rib on right is a small dark area, possibly a gland, which is also shown in the radiograph.

CASE NO. 4.



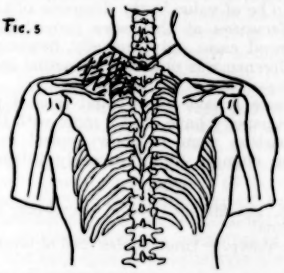
Girl, aged twenty-one years, house-girl, born in Nova Scotia.

*Family history.* — Sister had tuberculosis. Patient attended her during illness. Definite exposure.

*Past history.* — Measles, influenza.

*Present illness* (Nov. 26, 1907). — Six weeks ago lost her voice, last two weeks partially regained. Is considerably hoarse still. Cough, especially noticeable in morning, some expectoration. Easily tired. No loss of weight.

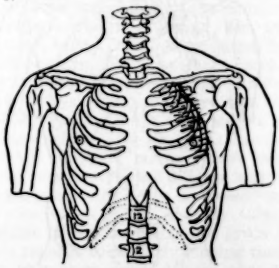
FIG. 4.



*Back.* Right apex: Dullness shown by shading. Breathing definitely prolonged and high pitched. Fremitus increased, especially whisper. No râles.
Excursion at bases equal and about one and one-half or two inches.

*Physical examination.* — Lungs affected. Temperature, 99.8°.

Diagram No. 4 illustrates the case. No tubercle bacilli found.



*X-ray report.* — Beginning tuberculosis at right apex.

FIG. 5.

*Back.* At left many coarse and fine snapping and bubbling râles with squeaks and grunts, chiefly with inspiration. Dullness shown by shading. Fremitus increased.

FIG. 6.

*Front.* Area of dullness shown by shading. Many coarse and fine snapping and bubbling râles. Squeaks and grunts chiefly with inspiration.

CASE NO. 5.

Girl, aged twelve years, school, born in Roxbury.

*Family history.* — Sister had pleurisy with effusion two years ago.

*Past history.* — Measles, pertussis.

*Present illness* (Dec. 14, 1907). — Coughing for two months, gradually getting worse. No expectoration. Night sweats. Chills. Dyspnea. Pain in left side. Breathes through mouth. Appetite poor. Subject to colds.

*Physical examination.* — Temperature, 99.6. Pulse, 84. Weight, 58 lb. Lungs affected. See chest diagram.

*Fluoroscope examination.* — Shadow in left upper quarter. Diaphragm lower on left side than on right. Excursion increased on right.

I wish to thank Dr. Francis H. Williams and Dr. Edwin A. Locke for the opportunity given me in making this study; also Dr. E. O. Otis for his valuable suggestions.

## THE NEUROLOGY OF APRAXIA.

BY GEORGE V. N. DEARBORN, M.D., CAMBRIDGE, MASS.

THE title chosen for this paper would be more properly "Suggestions toward the Probable Neurology of Apraxia," for in our relative ignorance as to the action mode of the brain no one may be quite certain of scarcely anything as yet relating to precise cerebral processes; much indeed hangs upon the nature of the nervous impulse. Does not Ramon y Cajal say under date of 1910 (Vol. II, p. 869, of his elaborate "Histologie"): "A dire vrai, il n'est pas possible, dans l'état actuel de nos connaissances, de formuler une théorie définitive du plan architectural et fonctionnel du cerveau"; and do not doctors as competent as Bastian and Ferrier diametrically disagree on nearly all essential matters concerned with the physiologic nature of the cortex? If one's suggestions, therefore, seemingly look forward and not backward, one need never be ashamed; and simplicity certainly we can never hope to find, but only the outline of the intricate plan.

In the usual discussions of the mechanism of voluntary movement (most of the actual research and thought have been classed as psychological), one of the most important factors of the complex neural process has been generally overlooked, namely, the spatial nexus in which all bodily action neurally considered has its rise. The more metaphysical discussions of movement have given it due consideration, but its physical basis in the organism has certainly been unduly ignored. It is to this as a factor in apraxia that the present writing intends to call attention. All apraxia includes ataxia!

As the writer has elsewhere (*Moto-Sensory Development*, 1910) in a general way suggested, observation of the development of voluntary movement in the infant during the first three years or so (a much-neglected medical field) indicates that power of deliberate action, save in the simplest innate movements of reaching and clasping with the fingers, develops *pari passu* with the conceptualization of space. This, we may not doubt, is much more than a coincidence. The infant is at first an all but reflex thing, moving under the stimulus of the inherent impulse to activity, and he becomes a free agent, personality, only as he becomes aware of the empirical three dimensions in which his body, like his wholly objective world, is constructed, and in terms of which alone initiative movement acquires meaning in any logical sense. In these terms alone to the finite mind is orientation or order; can any one, then, suppose that this universal ground of action is unrepresented in the integration of his will?

Physiologists more and more insistently are emphasizing the afferent or centripetal side of the motosensory circuits of the nervous system, as, indeed, our rapidly better appreciation of kinesthesia necessitates. For example, Wm. MacDougall, an English leader in the doctrine of muscle-action, in *Brain*, 1909, says, "The conception towards which the study of the organism as a whole points is that the neurones of the afferent side of the nervous system (including the cerebellum) constitute a great common reservoir of free energy, in which the head of pressure varies from moment to moment with the ratio of the inflow to the outflow, and on which all efferent pathways may draw in turn when they come into activity." So far as spatiality is concerned (surely in its relation to deliberate movement a case in point) the "reservoir" in the young infant's brain fills from many afferent sources indeed, and they, like other complex neural conditions, are beyond present exact detailing. Because he could not draw them wholly on the map, no one doubts that New England is covered with a network of railway tracks. Among the factors of this working knowledge of spatiality, however, in the evolving infant mind and therefore mechanized in the adult, are certainly these: A, the resident kinesthetic influences from the limbs moving so continually under the impulse to activity, and especially those coming from the joints, muscles, tendons, skin and bones of the arms and hands, pioneers in the evocation of the deliberate will. B, the kinesthesia from the extrinsic eye-muscles and from such other important and widespread muscles (of the neck, back, abdomen and even legs) as assist in directing the line of sight always on the (stereoscopically placed) foveæ centrales. C, the kinesthetic and special impressions integrating into equilibrium and coming from the semicircular canals, the eyes, and perhaps from the protopathic receptors of the abdominal viscera. D, in some way as yet hard to understand, the local signs of the surface and perhaps somewhat of the interior of the body, especially of the mouth cavity. E, the motor mechanisms of each of the senses so far as involving adaptive or adjustive muscular movements that afford awareness of direction or of space directly, for example the tongue, the retina being a conspicuous other example on the oldentime natavistic theory of spatiality. All these and probably other afferent influences gradually teach the baby that there is a *depth* for his deliberate exploration. A little later the kinesthesia from the locomotor mechanism, that of creeping, tumbling, walking, etc., enlarge and vigorously confirm the spatial concept thus in-

trinsically developed. Into the details of these various factors of original space-conception we need not even attempt to go, nor is it necessary to do so in order to be assured that their afferent impulses come from every portion of the body and directly or "symbolically" involve every portion of the brain. One need only consider how widespread is the visual "tract" through the hemisphere 'fore and 'aft; how expanded and how involved are the auditory centers if we include the essential vestibular functions; how spread-out and interknit are the taste-"centers," those of smell, of touch (shown by Van Biervliet recently to be a phase of kinesthesia), and of orientation, equilibrium and local signs. Such in the sketchiest of outline only is something of the brain-neurology, it may be, of the afferent intelligence that fuses into the fast-growing infant mind as a basal working knowledge of the space in which alone he can move and so have his being.

In proportion as the individual intimately knows this space as represented to him thus by the nervous system is he capable and skillful and efficient, master of himself and of his plastic invironment. In short, in the neural (and muscular) mechanism that develops originally a personality's notion of space we appear to have the foundation more or less of the neuromuscular mechanism of voluntary movement in its most obvious details and framework both at once, and what develops in the infant becomes the (often subconscious) determinant of the behavior of the adult.

Of course there is much more than this complex set of spatial neurograms that determines the co-ordination of the deliberate movements. Brain processes that represent concepts of objects (see below), of quality, of self-confidence, of interest, of relation of every kind, stand behind voluntary movement and these would be especially hard to localize in the cerebral cortex. There are furthermore relations to all kinds and degrees of emotional tones to be considered and innumerable and, in fact, indefinite connections with the intricate life's store of experiences.

> "Thoughts hardly to be packed
> Into a narrow act,
> Fancies that broke through language and escaped."

In short, the whole nameless and indefinable associated memory, conscious or subconscious, of the individual enters more or less, or may enter, into the immediate resolution of a deliberate action however trivial or important. All this means cerebral traces or cerebral action whose intricacy of pathway along the neurones no man can specify at present or even understand. The neurology of behavior in its sum involves all this and greatly more besides; motives and intentions, however well or ill-defined, could be really explained on certainly no simpler plan. Even if we may suppose some mode of simplification in the controlling neurogram of a simple voluntary act so far as the circuit around through the receptor, "motor center" and muscle is concerned, then even it would be, we may be sure, only a relative simplification, the work of "symbolic" knots of neurones that have undertaken familiar combinations in the course of years or centuries.

Besides all this, there must come out of the cortical maze, somewhere or at least somehow representing all this product of experience, the determination to make the movement at the time, perhaps the resultant of a host of afferent impluses from the relative periphery representing attentive effort. Lastly we may one day have to account for myriad intricate impulses that inhibit, — and this last presents a whole possible new field for neurologic search and research whose further boundary no one can as yet surmise and much less see.

Unless we cease to ignore the surpassingly complex determinants of voluntary behavior thus inadequately suggested we can in no wise even approach the solution of the neurologic problem. Here, as so often elsewhere, the first step to real explanation is appreciation of the intricacy of the conditions — and this the clinician too seldom stops to consider.

Apraxia has had various shades of meaning since Hughlings-Jackson first called attention to its interesting nature and the word later came into use, but at last there seems to be some general agreement to follow Liepmann's definition and to consider the condition "an incapacity for subjectively purposive movements of the limbs, with conservation of the power of movement." It is obvious that this conception is a broad and scientifically adequate idea notwithstanding its non-inclusion of voluntary movements other than those of the limbs; if one leave out of Liepmann's definition the words "of the limbs" the formula is exact and fundamental for all future discussion. Heilbronner's usage of the term includes various phases of the general condition but does not differ materially from this. On the other hand, the short and definite term "agnosia" for the failure to recognize objects has advantages that should make it regularly preferred (and used) to any expression that includes apraxis, for the two concepts are logically entirely distinct however close their alliance in clinical neurology. We discuss, then, in this essay in neurology, briefly as is fit, pure motor apraxia — a form of will-palsy basally unlike abulia.

Out of all the leading descriptions of apraxia (those, for example, of Liepmann, Bianchi, Heilbronner, Lewandowsky, Pick, Wilson, Coriat) two facts especially have eventuated — the reasonable probability of eupraxic "centers" in the two upper, especially the left, frontal lobes (above Broca's); and second, the frequent involvement of the corpus callosum in this particular form of will-defect. With the former proposition only are we here concerned, except in the general way allowed by our relatively scanty certain knowledge of the corpus callosum — to know which thoroughly would be to understand practically the whole of the cerebral cortex.

Many of the discussions of apraxia have clung perhaps somewhat too closely to the narrow clinical facts revealed by inadequate tests or to the still less informing conditions found in a few cases at the necropsy, thus ignoring generalities that are at once quite as certain and more instructive for general diagnostic use. As one may see from his above-quoted definition Liepmann has done better, for he discusses the condition on a basis that is not only clinical but thoroughly scientific and enlightening. It is then not only in the inability to use a few familiar objects, pencils and pocket-knives and the other things at hand on a physician's table, but it is likewise, and quite as importantly, in the patient's failure in voluntary movement generally involving no "use" of any thing outside the organism, that apraxia consists. In trying to extend his index finger outwards to touch the corner of a picture-frame on the wall a man may exhibit apraxia quite as well as in his ignorance of how to use a corkscrew or a thimble and yet the intended movement be apraxic and not merely ataxic. Indeed, for our present purpose, all voluntary movements or acts may be classed under two wholly arbitrary heads, namely, those that involve the using of objects whose use has been recognized, and those involving the use or practice of another object of consciousness whose basal nature the whole mechanism of efficiency recognizes, namely, *space*. Every voluntary act includes the use of this (universal?) spatial object, while only a relatively few base their co-ordination, following recognition, on material objects.

As the by-product of an apparatus — research under way in a somewhat different direction, it has recently been strongly impressed upon the writer how little the imagery experienced just before or during a careful voluntary movement has to do with the voluntary control as a performance in space with definite direction, speed, extent and force. Introspective reports in connection with exact objective records have made this matter distinct. Notwithstanding an essential identity of performance, the introspective experiences varied widely — the imagery of no two were alike. Kirkpatrick, Woodworth, Stout, Bair, Judd and many others before them as well as since have discussed imagery almost indefinitely, forgetful that consciousness, never lapsing, has to have some content, forgetful, too, as it seems, how competent a machine is the mechanism of human efficiency. No one in these days when psychologists, even, are beginning to understand what the subconscious is, should thus ignore the basal consideration that in the first years of life voluntary control became a well-developed psychomotor system competent to perform all ordinary movements, not new, with only symbolic control from centers working subconsciously whose function it is thus to direct familiar expressions of individual intention. The "reservoir" of afferent influences attends to the motivity of this, and consciousness only "says the word." The precise "imagery" that is attendant on a voluntary movement seems to have little effect on the accuracy of the movement save as it detracts from or increases the attention-effort exerted by the psychomotor (eupraxic plus the Rolandic?) centers on the musculature, on the particular action system in use at each moment. Out of the maze of brain and cord and sympathetic the deliberate will chooses for itself a pathway always complex and intricate. Physiologically the will is "viatility," but none the less human or divine on that account.[1]

Save in new and hence really difficult movements, much of the nerve-control apparently has been assumed by psychomotor-complex neurograms perhaps of the frontal lobes efferenting by way of the central convolutions, but, however, in a way the normal adult knows little of so far as direct experience goes. If, on the other hand, the motor idea of the action be intently conscious (as is always the case in really new co-ordinations) the attention is largely in terms of spatial relationship plus a more or less accidental and unimportant fusion of visual sensations; resident kinesthesia; ill-defined consciousness of effort or strains; and extraneous sense-impressions of many possible kinds. There is evidence that the resident kinesthesia may mean much in the acquirement of new and difficult control just as there is evidence likewise that in the average seeing person doing familiar things it means usually nothing at all for consciousness. In the blind the foundation space-consciousness is certainly much more definite and distinct than in normal individuals, as is also their resident kinesthesia (called by them touch). The relative inaccuracy of voluntary movement in the blind is not hard to understand when we consider the relative paucity, inevitable and great, of their eupraxic centers, products largely of experiences that they cannot have had.

The early elaboration of human behavior into very numerous psychomotor complexes on a basis of economy and habit devolves especially, we may reasonably presume, on two important portions of the brain (connected intimately, however, with all the rest) — the frontal lobes (via the central) and the cerebellum. If we know anything at all of the frontal cortex it is that one at least of its duties is this elaboration of motor ideas, how to use objects, for example, or how to rotate the arm or roll a shot between the fingers. These centers have in early years elaborated many such psychomotor complexes, have interrelated them, and have put them in bewildering intimacy with all the other centers in the brain and below it. Broca's convolution furnishes what is probably by far the most complex example of an eupraxic center, and its function is just the elaboration, interrelation, and extra-relation of a certain set of objects, namely, words. These, spoken, written, printed, graven, depicted, sculptured or materialized by the sign-manual constitute the physical basis, so to say, of the one uniquely human process of language-formation

[1] Some of the possible details of this neuromuscular process especially in the cord have been recently discussed by the writer in an essay on Attention in the *American Physical Education Review*, for November and December, 1910, and January, February and March, 1911.

and language-expression. Need one try to imagine the details of Max Mueller's speech-center in terms of neuraxones, dendrites, nerve-cells, or of ions and osmosis and reversing colloids? Yet this must be done some time and by some one or else all our fashionable localization be given up.

In a way quite homologous to this, every common object other than words must have representation in the frontal cortex, we may assume. If then a man does not know how to use a sextant or an eidograph or a planimeter, or a pencil or a pair of shears, it is so only because his frontal cortex has never acquired or, from disease, has lost that particular psychomotor complex. No more can be taken out than has been put in. As has been often well pointed out, the newborn child is almost wholly apraxic, although even then something in his mechanism of efficiency represents the use of his mother's breast just as it represents and provides the means of finding it in space. The cleverest adult obviously is he who has in his frontal cortex the greatest number and the greatest perfection of detail and relationship of these motor ideas (neurograms) of movements of utility.

Voluntary movements of the other of the two suggested classes, those not involving the use of particular material objects, employ a center commensurate in elaboration and universality of use with the "object" that they do employ, namely, space. The first part of this paper has tried to briefly suggest how manifold and complex and withal how fundamental is this spatial ground of all our neurally controlled behavior; we make our space and cannot move outside of it. We have already mentioned the most important of the factors that fuse into our voluntary development and give us the basis of our deliberate activity. The "center" of this voluntary nexus of movement is undoubtedly in some manner the cerebellum under the continual control of supranuclear influence. To leave the cerebellum out of any discussion of the neurology of apraxia is to dehamletize, so to say, the text, for without this all-related center voluntary movement has no principle of action, no rule of conduct. It needs only a drunken man reeling home or other afferent ataxia to demonstrate the proposition. We can almost, then, speak of the cerebellum as the space center, at the physiologic foundation of all voluntary movement, its "immanent idea."

Through the ipselateral pons each frontal lobe is in close connection with the contralateral lobe of the cerebellum. We may, therefore, be reasonably sure that the so-called eupraxic centers of the frontal cortex receive therefrom continually the nervous co-ordinations by which alone they can control the movements made in using objects. It is in making this connection between the hind-brain and the fore-brain that lesions of the corpus callosum may be involved in apraxia, as has recently appeared to be sometimes the case, for thus the space-co-ordinations of the contralateral lobe of the cerebellum might be cut off from the eupraxic centers, — for example, those coming from the right cerebellum to the left frontal lobes. This is the more important because lesions in the latter region have recently been found coincident with apraxia oftener than any where else.

It is difficult, however, to accept one suggestion made in current apraxic discussions, that, namely, of a single dominant center of eupraxia controlling all the rest. By the logical nature of use, unique for each kind of object, this idea seems to be untenable. If such a center be postulated, its most likely position would be in the Rolandic region where the general psychomotor co-ordinations of voluntary action are commonly supposed to arise. To cite Broca's center as an homologous instance of dominancy were to ignore the unequalled complexity of language and of language-expression. This center, if for convenience the term be retained for it, is in reality a large and intricate region of interwoven neurones out of all comparison with the requirements of a center that may be thought of as dominating numerous other centers each with co-ordinating duties of its own. In some such way as this altogether, the nature of the observed administration of the voluntary movements said to be defective in the clinical histories of actual apraxias may perhaps be tentatively better understood.

In many voluntary movements, then, spatiality seems to constitute the neural motor idea necessary for their co-ordination and muscular accompaniment, but in the movement of using an object space may be oftentimes only of secondary importance, although, we may presume, always underlying the cortical associations in its influence on the actual innervations. When the clinical observation of apraxia is regularly extended to cases or aspects presenting apraxic movements other than those concerning the use of small familiar objects, it can hardly be doubted that this important relationship of space-conditions will promptly appear.

The importance of the neurology of apraxia, as set forth by all recent writers, in relation to the baffling educational problem of ambidexterity presents itself for consideration, and the problem itself urges solution by comprehensive experimental methods.

## ACCURATE OPTICS.

BY ISAAC HARTSHORNE, M.D., POUGHKEEPSIE, N. Y.

EXISTING inaccuracy in optical production and the failure on the part of many oculists to recognize the same. — Trial lenses. — Prescriptions inaccurately filled. — Opticians and oculists both to blame, especially the oculists, since the responsibility to the patient is theirs. — Absolute accuracy can be obtained when demanded and the finished lens properly inspected by the oculist. — The commercial element. — The remedy is for oculists to verify the claims of accuracy of optical houses.

THE progress of medicine and surgery during the past thirty years has been so tremendous and so revolutionary that it must be difficult for most medical men of to-day to realize what it meant to practice medicine and surgery in and before the eighties. Suffice it to say that surgery is now aseptic instead of septic; diphtheria, smallpox and yellow fever have none of their former whole-

sale raids; tuberculosis is on the wane; and puerperal fever is considered practically mal-practice. Not one of these changes for the better was accomplished without a struggle, and at each progressive step some branch of medicine and surgery has had to clean house and start again. At the present time, the Council on Pharmacy and Chemistry is giving us a continuous performance of drug frauds, both in the line of proprietary medicines and also in the line of variations in strength of products put on the market by reputable chemical manufacturers.

There exists to-day in the world of optical production a condition calling for housecleaning and revolution just as strongly as any call issued in the past for better medicine and surgery. It is a condition calling for action along the same lines as the exposures by the Council on Pharmacy and Chemistry of errors in strength of drugs put out by reputable drug houses. It is, in short, a condition of inaccuracy in the products of many optical houses and many opticians and the failure on the part of many oculists to recognize these inaccuracies when they exist.

Let us begin with trial lenses. Cases of trial lenses are put out by optical houses at a cost of $35.00 and up. Several opticians have admitted to me that these cases are made in a hurry and are "probably not perfectly correct." I know of several oculists who have taken the trouble to go over their trial lenses carefully to determine their accuracy, and have found them anywhere from 10 to 50% wrong. Some of these cases were special orders and some stock cases. A year ago I ordered from a leading optical house a set of trial lenses made according to my own specifications and no price was named until the case was completed. The chief specification was that the case was to be absolutely accurate, both in strength of lenses and in the marking of the axes of the cylinders. The case was delivered in six months, cost about three times as much as an ordinary one, and was pronounced by the company as absolutely perfect. As to the accuracy of strength, only one lens failed to neutralize as it should do; but out of 208 cylinders, 34 were wrongly marked, that is, nearly 17% were wrong. Some of these errors were between 2 and 5° and two as high as 15°. In some of them the axes were marked on the true axis of the cylinder, but the marks did not run through the diameter of the circle, that is, the marks were not 180° apart. I believe this company intended to give me a perfect case and I have so expressed myself to them, and I believe that when this case left the factory it was above the average in accuracy.

To quote from "Current Comment"[1]: "The question arises: if a firm is careless enough to make incorrect statements to the Council on Pharmacy and Chemistry which it knows will critically examine the claims, what degree of 'carelessness' may be expected when the products are exploited direct to the physicians?" A similar question: if one of the best optical firms in the country puts out a case of trial lenses at three times the usual price and pronounces them absolutely perfect, knowing that this case will be carefully inspected as to its accuracy, and after such inspection the cylinders in that case are found to be nearly 17% wrong, what degree of accuracy may be expected in cheaper cases which are admitted to be inaccurate because of hurried preparation?

Oculists who use a mechanical axis finder and centering machine will admit that it is common to see patients wearing lenses that do not agree with their prescriptions, and in some cases in which I have been unable to see the former prescription I am quite ready to believe that the oculist did not prescribe the glass that is being worn. For example, to cite one case among many: A patient came to me from an eminent oculist, who, by the way, has no mechanical axis finder or centering machine, and she was wearing two pairs of glasses, distance and reading; the axes of the distance lenses were both exactly 86° and both lenses were decentered; the axes of the reading glasses were 80° and 90°, and each lense was so decentered that she also had a 1° prism base out in each eye. Since I found her axes 85° and 90° and she had orthophoria with the proper correction, I could not believe that the former glasses were as prescribed. The oculist had seen these glasses and had told her they were all right. If he had had such a device as above mentioned he could have discovered readily the several errors, and the success would have been his instead of mine. I also happen to know that this oculist's lenses are ground by a New York City firm which boasts of the accuracy of its productions.

A few months ago, while talking with the head of the most accurate optical house in New York City, he said to me, "When an oculist like Dr. Wm. M. Richards, of New York City, who is supposed to know little or nothing of the actual mechanics of lens grinding, can show us, who have been in the business for years, where we are making mistakes, it is high time for us to learn new methods." That house is now producing accurate work, at least to those oculists who demand accuracy and who use in their own offices axis finders and centering machines to check up the optician's work. When I began to demand accurate optical work in this locality my own optician, who has always been anxious to help and to please, found himself in the same fix as the New York firm, and had to learn some things over again. In a number of cases he has had to regrind one or both lenses, and in one case he ground six pairs of lenses before he got one pair that he said he knew I would accept, and he added frankly that any one of the six ordinarily would have passed, and yet only the last pair were ground accurately. I had difficulty with the New York firm referred to until they learned that the lens might as well be right first as last.

It is very easy to say the opticians are to blame for all this and should be treated accordingly. There is, however, a good deal to be said on their side which throws back considerable blame on the

[1] Jour. Am. Med. Asso., Feb. 11, 1911, p. 427.

oculists. If oculists were prepared to demand accurate optical work, and to determine its accuracy, in their own offices, in the form of the finished product, a great deal of this inaccuracy would disappear. By the use of an up-to-date axis finder and centering machine, accurate optical work,— and by "accurate" I mean not simply the correct strength of spheres and cylinders, but also exactly the correct axes of cylinders and the centering of lenses so that the optical center rather than the mechanical center can be placed in front of the pupil of the patient's eye,— is not simply possible, but should be absolutely required. It has been frequently demonstrated that when such accurate work is demanded it can be obtained, and when it is not demanded and the finished lens tested by the oculist it often is not obtained. Many oculists do test the strength of the lenses by neutralizing them with their own trial lenses, — which may or may not have been corrected, — guess at the axes of the cylinders within 15°, and pay no attention to the optical center of the lens. Such men often get the axes 5 and 10° or more in error of their own prescription, and also give prisms from decentered lenses, because the optician knows that they pay little attention to the real axis and optical center. Yet these same men admit the necessity of having the axis of astigmatism properly corrected and spend valuable time in trying to find that axis as nearly as possible.

Such being the situation, it would seem that a good deal of blame should be on the oculists themselves in not demanding accurate work and in not proving the claims of accuracy made by optical houses. The prescription is given by the oculist, and the oculist is responsible to the patient to have that prescription correctly filled. If, as in the case of lenses where the accuracy of the product is so easily determined, the prescription is not filled as accurately as the best and most modern methods make possible, the patient is being defrauded, in that he is not getting his full value from the prescription, and he is still further defrauded in that a wrong glass is more likely to do harm than good.

Furthermore, the commercial element comes in very strongly. If we want a first-class article we have to pay for it, and the oculist who tries to make optical houses cut prices to the lowest possible level will get a degree of accuracy commensurate with the price paid. The custom of commission between optician and oculist should be condemned even more severely than between general practitioner and surgeon. The optician is a merchant and as such desires to please the oculist, but does not feel called upon to provide an article any better than the oculist demands, and those oculists who are satisfied with inferior work will never get accurate work done by any optical house or optician, and in consequence the patient is the one who suffers. Since general practitioners are daily sending patients to oculists for refraction, they should demand accurate work from the oculists just as the latter should from the opticians.

The remedy is simple but decisive. Every oculist should require his optician and optical house to use an up-to-date centering machine and axis finder and he should have the same device in his own office. Every oculist should correct, or have corrected, his own trial lenses, both as to neutralization and as to axis marks. That is, the axis marks should run through or parallel to the axis of the cylinder and also through the diameter of the circle, and so be exactly 180° apart. I consider it absolutely essential to remove all cylinders below + 0.75 and — 1.00 from their frames in order to mark their axes correctly, since in my own case most of the low cylinders that were found to be wrong after removal from the frames had appeared to be all right while in the frames. No oculist should permit any patient to wear his prescription until the lenses have been checked in detail in the oculist's office and replaced if found wrong in any particular. Still greater perfection will be reached if the oculist follows the suggestions outlined in "Perfect Optical Work."[2] It is to be remembered that none of us are infallible and that even with a machine at the factory and also in the optician's shop a careful oculist will still at times find errors by his office machine.

We all refuse to accept the conclusion of a board of health that because a city's water supply goes through a sand filter the drinking water of that city must be free from harmful bacteria, but absolutely demand frequent bacterial counts to demonstrate how well that filter works and the actual condition of that particular water supply. As long as oculists permit opticians to pull the wool over their eyes by saying that a lens or a set of lenses do not need inspection, but must be correct since they were turned out by an optical house of good reputation, just so long will the opticians be satisfied with inaccurate work and the oculists continue to get the blame justly due them for conditions now existing. There will be no improvement in the work of any one oculist until he is willing to recognize his responsibility toward his patients and become in himself a Council on Lens Inspection and check up every lens which he uses in his office or for which he writes a prescription.

The necessity of accuracy in optical production will be admitted by all who have done sufficiently accurate work to know the advantages to the patient of good work over bad. That absolutely accurate work cannot be obtained without the use of a modern axis finder and centering machine will be admitted by all who have used such a machine. The frequency of inaccuracy and the truth of the above statements can be demonstrated readily by a careful examination with an axis finder and centering machine of a couple of dozen of lenses containing cylinders selected at random. Is it not, therefore, high time for the refraction branch of ophthalmology to clean house, to remove the stigma of inaccuracy and to start a new era of accurate optics? It is for the oculist to decide.

## AMERICAN GASTRO-ENTEROLOGICAL ASSOCIATION.

FOURTEENTH ANNUAL MEETING, HELD AT THE BELLEVUE-STRATFORD HOTEL, PHILADELPHIA, PA., WEDNESDAY AND THURSDAY, APRIL 19 AND 20, 1911.

(Concluded from No. 21, p. 758.)

### FURTHER EXPERIENCES WITH THE X-RAY DIAGNOSIS OF ULCERS OF THE STOMACH AND DUODENUM, EMBRACING FIFTY CASES; LANTERN-SLIDE DEMONSTRATION.

DRS. HENRY ADLER and HOWARD S. ASHBURY, Baltimore, presented this paper, which was read by Dr. Adler, who said that from a study of these cases, the following conclusions seemed to be justified:

(1) The retention of bismuth given according to our method for a period of over four hours signifies a pathological condition other than mere displacement.

(2) The absence of a bismuth shadow from the stomach area examined in small isolated spots is not due to stenosis or simple dilatation, but to ulcer.

(3) While we believe that a distinct effect has been made in ulcer diganosis, a valuable sign has been developed, which, when present, will justify us in carrying out our treatment with assurance in otherwise doubtful cases; yet we feel that the x-ray examination should not at present be looked upon as giving by itself a final verdict, but rather should bear weighty evidence when taken in combination with the other clinical data.

The x-ray examination having shown a definite ulcer-shadow before treatment is instituted, its persistence or absence in later radiograms after the treatment should be an index of the result of such treatment. Some work has been done on this line, but our experience is too young to report data of value.

DR. HEMMETER, opening the discussion on the last two papers, referred to some similar experiments that he had done six years ago. The report of these was not accompanied with any illustrations, because he had no plates available at that time, the whole apparatus now in use being a great improvement upon that formerly obtainable.

DR. GEORGE E. PFAHLER, Philadelphia, said that adhesions might be detected by examining the patient in different positions, if the organs all moved decidedly, but that in some persons, especially those well-nourished, the colon did not move a great deal. He did not believe that such large masses as shown were indicative of being retained in gastric ulcer.

DR. ADLER explained that no large masses of bismuth representing ulcer of the stomach had been thrown upon the screen. The large masses represented ulcer in the duodenum, where it was impossible to get absolute immobility.

### NEURO-MUSCULAR AND SECRETORY CO-ORDINATION BETWEEN THE STOMACH AND THE DUODENUM.

DR. J. C. HEMMETER, Baltimore, brought out the following points: (1) Secretion in the duodenum is not augmented by the presence of hydrochloric acid on the stomach side of the sphincter pylori. The hydrochloric acid or its derivatives must enter the duodenum. There is a periodic undulatory secretion of the intestinal juices in the fasting condition.

(2) Psychic secretion of pancreatic juice occurs in man.

(3) Jejune or fasting peristalsis (Pawlow and Boldyreff) occurs in the human being, probably as a means of evacuating products of excretion. This cannot be observed by the bismuth and x-ray method, because the digestive tract is not empty when bismuth is given. Observations on duodenal and ileocecal fistulas show it, however.

(4) There is a relation between the presence of bile and pancreatic juice in the fasting stomach to

(*a*) Disturbance of reciprocal intervention between the sphincter of Vater and the gall bladder in enteroptosis and

(*b*) The normal jejune or fasting peristalsis of Pawlow and Boldyreff.

### A CONTRIBUTION TO THE KNOWLEDGE ON THE FUNCTION OF THE DUODENUM.

DR. D. KAST, stated that the bulbus duodeni frequently shows food retention, which can be seen on the fluoroscope, if bismuth is mixed with the food. The food retention is often associated with altered peristalsis of the pyloric portion of the stomach and is the explanation for a variety of subjective gastric symptoms. The duodenal food-retention has a diagnostic significance.

### DUODENAL ULCER.

This paper, by DR. LEWIS BRINTON, Philadelphia, was read by DR. WALKER in the author's absence. The main facts brought out in it were as follows:

The principal symptom of duodenal ulcer is pain. There are several remarkable features about the pain of duodenal ulcer that serve to differentiate it from any other kind of pain:

Hemorrhages, while quite frequent in small quantity, are seldom so severe or so productive of alarming symptoms as in gastric ulcer.

Vomiting occurs in one fourth of the cases and shows nothing of uncommon interest.

Tenderness over the stomach is usually pretty constant in its position.

Occasionally there are signs of gastroptosis associated with the ulcer.

Gastric analysis offers but little aid in the diagnosis. The pancreatic action is a factor in the sum total of our diagnostic evidence in duodenal ulcer. No claim is put forth that this test is pathognomonic but it does afford a link in our chain of diagnosis.

Most cases of duodenal ulcer should be treated surgically, but should the day arrive when these ulcers shall be diagnosed in their early stages, then medical treatment will be the rule, and surgery the exception.

The diagnosis having been established, the examination of the feces at frequent intervals for occult blood constitutes a valuable index to control the modification of the diet and surgical treatment.

### THE CAUSE AND RELIEF OF PAIN IN DUODENAL ULCER.

DR. JAMES TAFT PILCHER, Brooklyn, stated that as the result of a study of one hundred cases of ulcer of the duodenum that had been diagnosed and confirmed by operation, and of some experimental work on a series of dogs, he had reached the following conclusions:

(1) Ulcer of the duodenum reflexly excites an hyperacidity of the gastric juice; (2) the maximum amount of secretion of hydrochloric acid in the stomach is due to a direct chemical action (hormones), and is at its height from one to four hours after meals; (3) it passes into the duodenum as hydrochloric acid, there being no food four hours after meals for it to work upon; and (4) it does not excite a flow of the duodenal juice directly and is not neutralized by the small amount present.

The relief of pain in duodenal ulcer follows the ingestion of any substance into the stomach, which

neutralizes the acid gastric juice. This conclusion is based upon the following facts:

(1) Food taken into the stomach excites at once a reflex secretion in the duodenum; (2) the duodenal secretion is alkaline in approximately the same degree as the gastric juice is acid; and (3) this secretion is of sufficient quantity and concentration to neutralize the hydrochloric acid of the gastric juice.

### PERFORATION IN DUODENAL ULCER WITH REPORT OF CASES.

DR. J. A. LICHTY, Pittsburg, considered the diagnosis of duodenal ulcer as being essential for the prompt diagnosis of perforation. He reviewed some of the leading points necessary to make a diagnosis of chronic ulcer, and referred to the distinction between acute perforation and so-called subacute and chronic perforation. From observations in the operating-room, as well as in the autopsy-room, he thought that it could be readily seen how an acute perforation not operated upon might not necessarily be immediately fatal. For this reason, perforating duodenal ulcer was frequently unrecognized. He reported a case illustrating this point, and also one of acute perforating duodenal ulcer that before operation had presented the symptoms of cholecystitis.

### HYPERCHLORHYDRIA AND PYLORIC OBSTRUCTION DUE TO CANCER DEVELOPING IN DUODENAL ULCER.

DR. A. L. BENEDICT, Buffalo, stated that the lesion had probably existed quite a while before the beginning of the period covered by the history, six weeks. There were no marked gastric symptoms. It was not until sudden collapse took place that the real state of the patient's nutrition was realized. The ischochymia was appreciated. The absence of liquid bowel movements was attributed to organic pyloric obstruction of some kind, even before the momentary feeling of a tumor, but it was obvious that the obstruction was not absolute. Owing to the distortion of landmarks, the questions of gastric dilatation and hepatic contraction were not answered by the physical examination. While the extracted stomach contents were abnormal, they were well within the limits within which one is justified in speaking of gastric dilatation. Owing to the restriction placed on the post-mortem examiner, neither question was positively answered at necropsy.

The question of cancer arose early, and this diagnosis was considered highly probable at the outset; but with the demonstration of a degree of free hydrochloric acid this diagnosis of carcinoma, unless in its incipiency, did not seem so probable, until the tumor was felt. In the author's experience, every case in which food has been retained in the stomach over twenty-four hours has proved to be malignant, but even considerable degrees of ischochymia do not warrant the diagnosis of malignancy. The location of the lesions in the duodenum, even the pyloric tumor being an invasion from the duodenum, explained the inconsistent findings. There was no history of bloody or dark passages. Apparently the ulcer had not bled recently, but no fecal matter was available, and the duodenum obviously could not have been invaded through the stomach.

DR. ROBERT T. MORRIS believed that Dr. Kast's work would give an opportunity to make a diagnosis in these cases of cobwebs in the attic of the abdomen, which occurred most commonly from the influence of toxins taken from the colon by the efferent vessels of the portal system and excreted by the liver. He considered that both hypersecretion and hyposecretion meant a derangement of the hormones through deranged hematin secretions acting on the area of the bowel secondarily from adhesions throwing off endothelium of blood vessels, and causing proliferating endarteritis of terminal arteries.

DR. FUHS stated that if the urine of a patient suspected of malignant disease be examined by adding methylene blue and allowing this mixture to stand in a test-tube from twelve to twenty-four hours, the blue would be found decolorized when malignant disease was present, but not if it was absent. Those few other diseases in which it is decolorized can readily be differentiated from malignancy.

DR. DUDLEY ROBERTS, Brooklyn, considered Dr. Einhorn's string-test of value, but said that it might fail when dealing with ulcer not at the pylorus or at the lesser curvature of the stomach.

DR. KAUFMANN questioned whether it was worth while to differentiate sharply between duodenal and gastric ulcer, the only difference being their location. What was desirable, too, was that an ulcer was present, and it would be more desirable to know the pathogenesis of these processes.

DR. EINHORN thought it often of great importance to find out the source of the hemorrhage.

DR. A. G. GERSTER considered the principle of making a precise diagnosis perfectly correct, but thought that the essential thing was to know that one is dealing with ulcer. He endorsed the statement of Dr. Lichty that the perforation of a duodenal or gastric ulcer does not involve immediate danger.

DR. C. J. JOHNSON had noticed marked disturbance of vascular action in several cases that at first had no subjective symptoms of ulcer.

DR. BENEDICT was glad no one had said that every case of hyperchlorhydria signified duodenal ulcer. He preferred bismuth to kaolin. He thought that the fluoroscope would give a better idea of the motions of the stomach than the x-ray plate.

DR. LICHTY had found definite ulceration below the papilla. He believed that a study of uremic duodenal ulcers would give valuable information. In using the string-test, he had found that in cases of carcinoma the blood-stain was long, while in ulcer it was minute.

Dr. WALTER B. CANNON referred to a case of reversed peristalsis of the end of the stomach that he had reported. It occurred after having given mustard, showing that there was a relation between reversed peristalsis and nausea.

### A STUDY OF SIX CASES OF SO-CALLED LARVAL HYPERACIDITY.

DR. JULIUS FRIEDENWALD, Baltimore, said that cases are not uncommon in which symptoms of hyperchlorhydria exist, and yet the gastric contents show a diminution or a complete absence of hydrochloric acid. This condition is explained on the basis of a gastric hyperesthesia. In addition, there are a certain number of cases manifesting similar symptoms, in which the gastric contents present a normal or a lessened proportion of acid; and yet in which, during the earlier periods of digestion, a hyperchlorhydria is at hand. Roth and Strauss first drew attention to this condition, but it was more carefully investigated by Schuler, who termed it "hyperaciditas larvata."

In the larval hyperacidity, there is an actual hyperacidity, which is often not revealed, inasmuch as the gastric contents are not extracted early enough, for the secretion, which at an earlier period would present a hyperacidity, is gradually neutralized before the end of an hour when taking an Ewald test-breakfast. Observations over a series of six cases have been made. Test-meals were given, and removed at varying intervals; and while the percentage of free hydrochloric acid was normal, and subnormal at the end of an hour

after an Ewald test-breakfast, yet it was found that there was a period in which a hyperchlorhydria was manifested.

GASTRIC HYPERSECRETION.

Dr. Arthur F. Chace, New York, stated that the results regarding the secretory function of the stomach obtained by the original Ewald-Boas test-breakfast are not so conclusive as they were originally assumed to be, mainly on account of the closely interrelated and overlapping effect of motility and secretion. In this respect, the dry test-breakfast, as proposed by Boas, eliminates certain features. The results obtained from more than two hundred tests throw light on the extent to which secretion is influenced by motility and suggest that in cases of disordered motility the dry test-meal is a more accurate index of the secretory function of the stomach than is the wet. The rôle of fatigue in gastric function is important.

A NEW TEST-BREAKFAST.

Dr. Dudley Roberts, Brooklyn, considered the Sahli test-meal and its modification by Friedman, for the estimation of the actual residue of test-meal and secreted gastric juice, to have inherent disadvantages dependent upon the use of a fat-emulsion. The writer suggests the use of lactose added to weak tea to the strength of 10%. After the lapse of one hour, a portion of chyme is extracted, and water in known amount added; and a second extraction is performed. By the Mathieu-Raymond formula, the total residue is calculated; and by the estimation of the lactose present, the amount of test-meal remaining is accurately determined. The estimation of the lactose in such a solution is simple. It would seem that the method, because of its simplicity and accuracy, might be worth general adoption.

Dr. Fuhs, opening the discussion on the last three papers, asked whether any correction should be made on account of the sugar that comes through the saliva.

Dr. Kast said that it could be demonstrated that there were two separate secretions going on, one induced by psychic stimulation and the other the gastric juice. In about fifteen minutes after ingestion or sham-feeding, the former, or appetite juice, would be at its height; the secretion of gastric juice does not begin until the food reaches the stomach, its curve rising for a while and then gradually going down, and usually disappearing before the end of an hour. Increased stimulation of gastric secretion due to psychic stimulation is usually found in the beginning rather than at the end of digestion.

Dr. Benedict stated that the secretions normally came up with varying rates into the stomach, and also varied according to the diet and the closeness with which the test-meal represented the ordinary food of the patient. He wished the members to discuss the hypothesis that in cancer there is such activity in the stomach that all the hydrochloric acid is used up, as opposed to the older view that none is produced.

Dr. F. W. White, Boston, wished to know whether in the cases in which the acid came earlier, the pain was also earlier.

Dr. Friedenwald stated that within an hour the pain had appeared, and that in an hour and a half it had vanished.

Dr. Chace had found that both the dry and the wet breakfast showed the automatic regulation that goes on between motility and secretion, in bringing the end results to the same point. He had purposely avoided the use of carbohydrates, because of the rapidity with which they passed to the small intestines.

Dr. Roberts replied to Dr. Fuhs by saying that the objection constituted by the food coming through the saliva had occurred to him. He hoped to be able to answer the question by the next meeting. He considered his test-meal of considerable value on account of its simplicity, the ease with which one could estimate the sugar, the pleasantness of the meal to the patients and the fact that it would give an actual knowledge of the muscular power of the stomach.

Dr. Meltzer stated that experiments on animals by v. Mering and his pupils had shown that sugar is absorbed from the stomach.

Dr. Cannon said these observations had shown that the absorption had occurred only when sugar was present in rather high excess, and he thought that it would be a question as to the percentage in which sugar was present in the meal of Dr. Roberts.

Dr. Roberts agreed with Dr. Cannon, and stated that if he could establish a constant error in regard to the sugar, it would be just as satisfactory as if there were no error.

A NEW SIGMOIDOSCOPE.

Dr. Dudley Roberts thought that sigmoidoscopy should be an important work of the gastro-enterologist. He had made it a routine part of the examination in cases of disturbed function of the bowel and others in which it is indicated. In this instrument, the obturator is much more olive-shaped than in the other forms of sigmoidoscope and proctoscope. It is a foolish idea that obturators must be made rounded, because it is dangerous to shove anything with a sharp point into the bowel, for the instrument is not introduced any further than the anus. There is in this sigmoidoscope a side tube, carrying a small light, the light-holder being standard in all instruments. The rays are passed down, and, by reflection, become parallel. At the proximal end of the instrument, there is a window, which is screwed on. The glass is the full size of the lumen of the tube. Therefore, there is no obstruction whatever to the view. There is another small tube for connection with the rubber dilating bulb. It is surprising what a bright light one can get with this instrument, and it apparently works as well in a small caliber tube as in one of larger caliber. The light is thrown two or three inches from the end of the tube, which is as far as the curve in the bowel will allow one to see. The instruments are made in four sizes.

Dr. Benedict thought Dr. Roberts had done well to get rid of the sidewise projection, which interfered with the rotary movements of the sigmoidoscope. The light also reflected well. Dr. Benedict had found it advantageous to be able to get the light adjusted right down to the point he wished to examine. He did not see any reason to inflate the intestines, except for the purpose of inserting the tube.

Dr. Fuhs considered this instrument superior to any that he had seen in simplicity and in answering the purpose for which it was designed.

Dr. Thomas Charles Martin, Washington, D. C., did not believe that he had seen the sigmoid flexure in more than 5% of the cases that he had examined, owing to the fact that when the sigmoid inflates, it often approaches a point nearer the anus than is the upper end of the rectum.

Dr. Roberts explained that the inflating bulb was not used so much to inflate as to puff folds of mucous membrane out of the way. He thought that Dr. Martin was rather conservative in his estimation of the number of times that he had been able to get into the sigmoid.

FURTHER EXPERIENCE WITH THE BENZIDIN TEST FOR OCCULT BLOOD IN DISEASES OF THE DIGESTIVE ORGANS.

DR. F. W. WHITE, Boston, gave a review of the literature of the subject, and referred to the results with the Schlesinger and Holst modifications of the benzidin test in several hundred recent cases. He described the technic of the test, and stated that he did not consider it over-delicate, a large number of negative results having been obtained. In feces, positive results were obtained only with ulcerative lesions of the gastro-intestinal tract and hepatic cirrhosis. The benzidin test has many advantages over the guaiac test. The author also made a brief comparison between the benzidin test and the phenolphthalein test for occult blood.

DR. ALBERT BERNHEIM, Philadelphia, stated that within the last few weeks he had tried a new test with fluorescin which acted in the same way as phenolphthalein and was more delicate than the latter in some cases.

DR. ROBERTS had come to the conclusion that positive findings were of great value in the benzidin test, but that negative findings indicated comparatively little. Several times he had been much confused because patients had taken hemoglobin preparations, and he had had to guard against this source of error with great care.

DR. FUHS stated that in testing for blood in the stomach contents, he always tested the saliva also for blood. Benzidin added to stomach contents, he further stated, seemed to have the property of liquefying mucus.

DR. BENEDICT had found several cases in which the occult blood in the feces came from a spot but ten inches above the anus.

DR. WHITE thought that both the positive and the negative findings had a good deal of value. If in patients with suspicious symptoms he found no occult blood after they had had time to develop cancer, he considered this good evidence against the existence of malignant disease. He considered positive results in the feces of much more value than the same results in the stomach contents.

LYMPHOCYTOSIS IN CERTAIN GASTRO-INTESTINAL CASES.

DR. JOHN P. SAWYER, Cleveland, Ohio, said that in practically all his cases, for several years, a differential count had been made under his own control; and in the course of these observations he had often found the differential count of clinical advantage. He did not refer in this clinical study to established departures from normal counts, as found in the known so-called blood diseases; he wished to speak more especially of the considerable variations from the usually accepted average differential counts in adults; for in children we have the known mononuclear lymphocyte counts in high proportion. The average lymphocyte count is about 30%. A slight variation from this is not of considerable moment, but when the lymphocyte count rises to 40 or 50%, this is probably indicative of a considerable departure from the usual blood formation. The lymphocytes are the product of the lymph tissues, discharged into the blood. Therefore, from a study of cases of high lymphocytosis, it is possible to gather information regarding possible stimulation of lymphatic tissue. These large lymphocyte counts are found without leucocytosis in a considerable number of diseases; among them, cases of gastro-intestinal disease. It occurs in cases in which gastro-intestinal catarrh is not discoverable by examination of the test-meal or of the stool, and in which the history shows no record of the existence of such catarrh recently. The condition of the gastric secretion seems to have no determining influence upon this lymphocytosis. It is usually found in persons whose resistance is low. In such cases it is possible, by treatment of the patient, to bring about a very prompt and decisive change in this lymphocytosis. This treatment consists in the administration of iodide of iron for a few weeks and the exhibition of arsenic. This treatment brings about a prompt reduction in the lymphocyte count, and the patients gain rapidly in weight and strength.

DR. MELTZER had come to the conclusion that there was a difference in the ferment between the leucocytes and the lymphocytes, on acting in alkaline, and the other in acid media; and he thought that there might be a definite relation between certain conditions of acidity and lymphocytosis.

DR. SAWYER said that he would be glad if Dr. Meltzer could work out any connection between the two.

IS PELLAGRA A DISEASE PRIMARILY OF THE ALIMENTARY TRACT?

DR. J. C. JOHNSON, Atlanta, considered pellagra to be a disease distinct from all others, and stated that it is not acute in the sense that idiopathic fevers are. Its duration is strangely variable. Necessary to its development are certain positive conditions of the organism; chiefly a disturbance of inorganic balance. These conditions are emphasized with the progress of the disease. It often exists long before it is recognized or suspected. Gastro-intestinal symptoms are usually the first to appear, and are in proportion to the gravity of the attack. There is an absence of hydrochloric acid in advanced cases; and in many, a lack of ferments. The cases were treated successfully with chloride of potassium, tincture of iron and essence of pepsin.

DR. MELTZER thought that the fact that the serious cases of pellagra had no hydrochloric acid and that the cases that had hydrochloric acid had no serious symptoms indicated that the cause of the disease was of a kind that had to pass the stomach. If hydrochloric acid was present in sufficient strength there, the disease would not develop.

DR. BENEDICT expressed the opinion that there was absolutely nothing specific or in the nature of an entity about pellagra. He considered cases of it nothing but ordinary senility, insanity, skin-eruptions of various and all sorts of toxemias.

DR. JOHNSON replied that if Dr. Benedict had ever seen a case of pellagra, he would have no doubt of its being a distinct disease. In Dr. Johnson's cases, the usual remedies were not employed at all. He merely gave potassium chloride, tincture of iron and essence of pepsin, and all the symptoms were usually relieved in a week's time.

DR. MELTZER said that such a statement as Dr. Benedict's should not be made in an offhand way. For instance, four years ago, no one would have considered poliomyelitis a disease entity.

DEMONSTRATION OF A CASE OF VOLUNTARY AND INTENTIONAL REGURGITATION.

DR. ALBERT BERNHEIM, Philadelphia, stated that the patient, a young physician, can regurgitate food voluntarily and intentionally, whenever he desires to relieve symptoms of gastric distress. He usually takes a glass of water, to liquefy the contents of his stomach, so that they may come up easily; and also takes some bicarbonate of soda, so that the acidity of the regurgitated material may not injure the mucous membrane of the throat and mouth. He then bends over, so that

the abdominal muscles compress the stomach. The esophageal opening of the stomach then dilates, and the food comes out.

Dr. Meltzer said that he could hear what he called the second deglutition sound, which occurred immediately after the beginning of swallowing, indicating that the cardia was patent. He considered this the reason why the patient could relieve himself so readily of the contents of the stomach.

Dr. A. Owaroff, Philadelphia (the patient), said that if the cardia were always open, he would get some fluid in his mouth when he bent down, but that it was only when he wished it to do so that the fluid came up into his mouth.

Dr. Meltzer explained that a patent cardia did not mean one that was always entirely open. It had a moderate degree of closure, which was overcome by a very slight stimulus, such as that afforded either by the beginning of deglutition or by the pressure with the abdominal muscles. He was not inclined to believe the opening of the cardia voluntary.

Dr. L. M. Gompertz had a patient who was able to regurgitate his food. On one occasion, this patient had had an attack of complete reversed peristalsis, vomiting turpentine five minutes after it had been given by enema. He recovered from this attack without treatment.

### CONSTIPATION WITH DIARRHEA.

Dr. Albert Bernheim, Philadelphia, said that some varieties of constipation are found in cases of gout after operation (adhesions, kinks, spasms); some are found in tuberculosis; and others manifest themselves, not as constipation in the usual conception of that condition, but apparently as cases of diarrhea. There are symptoms of auto-intoxication (vasomotor ataxia) and nervous conditions; also symptoms simulating appendicitis. Tests should be made for peristalsis and fecal matter. The treatment is medicinal, physical, hygienic and dietetic.

Dr. Fuhs, in connection with the difficulty in differentiating between appendicitis and stagnation and impaction of fecal matter in the cecum, mentioned the fact that there is a point of marked tenderness at the second intercostal space in the latter condition, on a line drawn from the middle of the clavicle downward.

### MITRAL MURMURS IN GALLSTONE DISEASE.

Dr. David Riesman, Philadelphia, stated that in a number of cases of gallstone disease he had heard a mitral systolic murmur during and shortly after an attack of colic. He had found these murmurs perplexing when the advisability of operative treatment was to be weighed. In all the cases seen by him, the murmur had not existed prior to the attack of colic. It was not due to endocarditis, for it disappeared soon after the attack. It was not due to anemia; and it was not due to jaundice, because it could be heard in cases that did not have icterus. It probably depended on temporary dilatation of the heart. Dr. Riesman believed that the chronic disease of the biliary tract, with its accompanying infection, had caused a myocardial degeneration, somewhat akin to that found in connection with fibroid tumors of the uterus. The degeneration predisposed the heart to dilatation when, during the attack of colic, the blood-pressure rose. The murmur was loud and unmistakable. The heart was enlarged, but not to any great degree. Dr. Riesman did not consider the presence of the murmur any contra-indication to surgical intervention. Indeed, if the pathogenesis was as stated, it would constitute a point in favor of operation. Care should, however, be taken in giving the anesthetic.

Dr. Meltzer drew attention to the fact that sometimes, a murmur would exist in association with pain so excruciating as to lead one to believe it due to some trouble with the gall bladder, while it was really a symptom of angina pectoris. He had no doubt, however, that in Dr. Riesman's cases there were definite evidences of the existence of gallstones.

Dr. Fuhs had seen two cases of distinct biliary colic with asthmatic attacks in patients who had never had any asthmatic attacks before the attack of cholelithiasis, and never had one after it. There was no functional or organic disturbance of the circulatory system either before or after the attack of gallstones.

Dr. Riesman agreed with Dr. Meltzer that angina pectoris might manifest itself with pain in the epigastrium or upper abdomen, but stated that he had been speaking of genuine cases of gallstone disease.

Dr. Walter B. Cannon was re-elected president of the Association, and Dr. F. W. White, of Boston, was elected secretary-treasurer.

## Book Reviews.

*Biology, General and Medical.* By Joseph McFarland, M.D., Professor of Pathology and Bacteriology, Medico-Chirurgical College of Philadelphia. With 160 illustrations. Philadelphia and London: W. B. Saunders Company. 1910.

In preparing this book, McFarland has had in mind the general reader rather than the special student. To this end he has discussed biological problems in such a way as to be intelligible to readers who have relatively small acquaintance with the natural sciences. Finality is not attempted, but rather a personal expression of opinion. Particular stress is laid upon the questions of blood-relationship, infection, immunity, parasitism, inheritance, mutilation, regeneration, grafting and senescence, — all matters in which the laity has a wide and abiding interest. The probable value of the book to those contemplating the study of medicine justifies the sub-title, "Medical Biology." The text is entertainingly written and fully illustrated, largely by drawings. Although by no means an authoritative treatise on biology, to which, in fact, it makes no pretense, the book presents many subjects in such a way as to incite to further study and to popularize a fundamental branch of science.

*Pulmonary Tuberculosis and its Complications.* By Sherman G. Bonney, A.M., M.D., Professor of Medicine, Denver and Gross College of Medicine, Medical Department of the University of Denver. Second edition, thoroughly revised, with 243 original illustrations, including 31 in colors and 73 x-ray photographs. Philadelphia and London: W. B. Saunders Company. 1910.

This work on tuberculosis has been well received, as is indicated by the fact that it was reprinted in 1909 and revised and entirely reset in 1910. The first edition was reviewed at length

in these columns on page 589 in the issue of May 6, 1909. The errors to which we then called attention remain uncorrected in the present edition.

Five new chapters have been added and many sections of the work have been thoroughly revised. A large amount of information not given in other books will be found in this volume.

The portion of the book which deals with the treatment of the disease is excellent. The author sounds a needed warning against the employment of exercise as a therapeutic measure in the active stage of phthisis.

The work is a wiser guide on treatment than it is on diagnosis. As nothing is more important than the early recognition of pulmonary tuberculosis, the reader has a right to expect in a work of this magnitude a reflection of the best modern teaching. This he will fail to find. If the student is guided by the author in his examination and diagnosis it is safe to say that not a small proportion of incipient cases will not be recognized. Bonney, in this edition, as in the first, emphasizes the "vast importance of râles as a factor of early diagnosis." It is now recognized by the leading authorities, such as Kroenig, Turban and A. Fraenkel, in Germany, and Babcock, Brown and Minor in this country, that other physical signs precede the development of râles. In fact, Fraenkel maintains that when râles are heard the disease is no longer in its incipient stage. As Minor says, "One should under no circumstances wait until they develop before making a diagnosis."

The value of percussion as an aid to early diagnosis is not appreciated by the author. The truth demonstrated so clearly by the clinical and pathological studies of Kroenig and Oestreich that impairment of pulmonary resonance on *light* percussion occurs in the incipient stage of phthisis is still denied by the author. After showing by collected statistics that in about 50% of the patients with active pulmonary tuberculosis it is not possible to demonstrate tubercle bacilli in the sputum, Bonney adds that "there can be no greater dereliction of duty on the part of the physician than to withhold the diagnosis until the appearance of bacilli." With this sound statement in mind, it is surprising to read in another place that "save under very puzzling conditions, recourse to the old tuberculin of Koch by subcutaneous injection is quite unnecessary and unwarranted."

*Landmarks and Surface Markings of the Human Body.* By L. BATHE RAWLING, M.B., B.C. (Cant.), F.R.C.S. (Eng.). With thirty-one illustrations. Fourth edition. New York: Paul B. Hoeber. 1911.

This admirably illustrated volume, with a well-written descriptive text, presents clearly and concisely the surface anatomy of the body, and the surface relations of deep anatomic structures. An appendix contains the dimensions and weights of various organs. The book is a manual of standard value for students, teachers and practitioners of medicine.

THE BOSTON
# Medical and Surgical Journal.

THURSDAY, JUNE 1, 1911

*A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.*

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

*All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston.*

*All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.*

*Remittance should be made by money order, draft or registered letter payable to*

W. M. LEONARD,
101 TREMONT STREET, BOSTON, MASS.

## SOME MODERN ASPECTS OF ENGLISH RACE MIGRATION.

THE returns of the recent British census afford material for interesting study in the growth of populations and in the problems of race diffusion and evolution. Provisional figures indicate that the population of England and Wales has risen from 32,527,843 in 1901 to 36,075,269 in 1911, a net gain of approximately 11% during the past decade. This in itself would seem fairly gratifying, and should abate the apprehensions of some of the prophets of race deterioration, but unfortunately this gain in numbers has not been equalled elsewhere. The population of Scotland, now 4,759,521, has increased only 287,418 since 1901, a net gain of about 6.4%.

Everywhere in Great Britain the increase has been proportionately greatest in the large cities, but in Scotland even the cities have grown at less than half the rate of those in England. The population of London has grown from 6,581,402 in 1901 to 7,252,963 in 1911, a gain of 671,561, nearly 2½ times as much as that of all Scotland. This increase, it is said, however, has been largely in the peripheral districts of the city, a fact illustrating the tendency of modern populations to simultaneous aggregation and suburbanization. With the development of facilities for rapid transit, precisely this some phenomenon has been observed in our large American cities. Centralization and decentralization proceed together. It becomes possible more and more to combine the advantages of working in a large city, and sharing its educational opportunities, with those of living in a relatively rural district, having ready access to the city on the one hand, without the deprivation of civilized facilities

often associated on the other hand with life in the country.

While England and Wales have in this manner grown rapidly and Scotland slowly, the population of Ireland has diminished. The decrease, however, has been only 1.7%, the least of any decade for the past seventy years. It is particularly interesting that this decrease has been proportionately much greater among women than among men. The total number of males now in Ireland is 2,186,804, a decrease of only 0.6% since 1901; the number of females is 2,195,147, a decrease of 2.8%. The ratio of the sexes is more nearly equal in Ireland to-day than in any other modern civilized country. In Great Britain, women are far in excess over men.

The cause of some of these facts is not far to seek. The loss of population in Ireland and its sluggish gain in Scotland is an evidence not so much of race suicide as of race migration. The efflux of Irish population to the United States, which deserves to rank with the great racial movements of history, is the chief cause of the decline in Ireland, since the excess of births over deaths in that island still amounts to about 20,000 a year. The change in ratio of the sexes is apparently due to economic causes, the women being much more attracted by their opportunities for employment in this country than the men.

In Scotland migration also seems to have been the chief reason for failure to gain more rapidly in population. Great Britain's loss in this respect has been Canada's gain, for during this past decade 750,000 immigrants have come to Canada from the British Isles. Of these, it is true, 560,000 have been English and Welsh, and 150,000 Scotch; but these figures represent a proportionately much greater loss for Scotland than for England. During this same period Canada has derived 700,000 immigrants of English extraction from the United States.

The bearing of these facts on future history may be more important than at first appears. Such a migration should mean that the future civilization of Canada is definitely to be governed by Anglo-Saxon ideals. Coming at a time when there is so large an influx of alien Semitic and Latin peoples into our own country, it should mean the establishment of Anglo-Saxon institutions on a desirably firm footing in the great and developing nation on our North. That the civilization of this continent should be determined by the customs and traditions of our own race, we cannot but believe to be for the best. In its larger aspects, therefore, the relation of British population to our own and to that of Canada is of special significance, for it represents the continued dissemination to our continent of cognate racial stock and ideals. The migrations from the British Isles during the past decade are but part of the world-wide diffusion of the English-speaking people, whose unresting energy has in fifteen centuries carried their influence to every extremity of the globe.

## THE MAIN GATEWAY TO THE WESTERN WORLD.

"Don't hinder commerce; let the ships go up!" "Keep up the standard of future citizenship; don't let the incompetent get by!" These are the maxims established at quarantine in New York Harbor by Health Officer Alvah H. Doty and Dr. George W. Stoner, of the Department of Commerce and Labor.

It is the province of Dr. Doty and his assistants to detect and eliminate infection at the port of New York. The law requires them to inspect ships to this end between sunrise and sunset, but they know no sunset, and sometimes no sunrise. They are now on duty, one or another, all the time; and are ready to board a vessel any hour, day or night, it wants to enter the upper bay. Of weather, no account whatever is taken. When ships come in, one after another, they don't even have to anchor; oftentimes the vessel has moved well up into the harbor while the health officer is making his inspections.

It is indeed a dangerous occupation — that of safeguarding our people against meningitis, plague, cholera, yellow fever, smallpox, typhus and what not else. Dr. Doty has observed that "one is practically bound to go down sooner or later," catching a disease either on shipboard or in either the Swinburne or Hoffman Island hospitals. The death on March 21 last of young Dr. Edward F. Ashley from cerebrospinal meningitis evidences what may happen even when the most elaborate precautions are taken. A good health officer, in Dr. Doty's opinion, has no personal fear; "a man engaged in quarantine work who stops to think of himself is no good. My assistants are good; they are the cream of the hospital graduates of the city." And men must indeed be "good" who keep at the work day and night when the occasion demands, who are ever ready to meet any emergency, who detect the sick and the bacterium carriers, and still hold the ship no longer than is positively necessary. There is a most noteworthy enthusiasm about

these physicians; men have been called heroes for much less than they do.

This quarantine station is, perhaps, the best place in the world to study infections; there constantly arise complicated cases that cannot be duplicated in any European hospital. One half the shipping of the United States annually passes this station, and seven eighths of the immigrants who bless us with their advent pass through the Narrows. In a twelvemonth Dr. Doty and his assistants board all kinds of ships, from famous liners to rusty tramps that hail from what not potentially infective region. In seven hours of one day twelve thousand travelers were examined.

The detection of the obviously sick has ceased to be the main work at quarantine; every year more and more stress is being laid upon the bacteriological aspect of the work. The bacteriological staff are as enthusiastic in their work as are the boarding officers, the hospital physicians and surgeons and (let us by no means neglect to observe) the self-abnegating nurses. At quarantine they don't take anybody's word for anything. There is here no reflection upon the ability or probity of ship's surgeons; but when there has been sickness on a voyage, quarantine makes its own examination, bacteriologically if necessary. Here it has been established at first hand, for example, that persons apparently well may nevertheless be carriers of cholera vibrios; and by this means was cholera kept out of our country in the fall of 1910.

It is again most noteworthy that the federal government has now its agents in many European ports; indeed, a sure change is coming about in quarantine work; it will soon be practically all done at the ports of departure. Keeping the sick, and those who have been exposed to infection, off the boats before they sail is much cheaper, much more expedient, than quarantining them here or sending them back to Europe at the expense of careless and selfish ship owners. Moreover, one sick man, when the ship leaves Europe, is very apt to mean several cases of sickness developed during the voyage. Suspects are now being examined and detained at ports of departure; by this means, moreover, are the European companies spared the expense of treatment and housing for the sick and the suspects in the New York harbor hospitals.

Again, quarantine has demonstrated that live steam is the best of disinfectants, and that cargoes, moreover, do not convey disease. Quarantine does not now bother about cargoes; it concerns itself with persons and (except as to yellow fever) only with immigrants. Nor are disinfectants or deodorants used in cleaning in either the Hoffman or Swinburne Island hospitals; soap and hot water do the work; in addition, the floors are regularly painted and repainted with red lead.

At Ellis Island Dr. Stoner and his staff observe and "put the chalk mark" on the shoulders of all immigrants suspected of being "idiots, imbeciles, feeble-minded persons, epileptics, insane persons and persons who have been insane within five years previously; persons who have had two or more attacks of insanity at any time previously; persons afflicted with tuberculosis or with a loathsome or dangerous contagious disease; persons not comprehended within any of the foregoing excluded classes who are found to be and are certified by the examining surgeon as being mentally or physically defective, such mental or physical defect being of a nature which may affect the ability of such alien to earn a living." During the last fiscal year Dr. Stoner and his aids examined 741,590 steerage passengers and certified 19,545 for physical or mental defects.

## MEETING FOR THE BOSTON INFANTS' HOSPITAL.

IN the issue of the JOURNAL for May 18 we noted the present status of the new building for the Infants' Hospital, and announced the meeting to be held on May 24 in its interests. At this meeting, attention was called by the various speakers to the work already accomplished by the hospital during the past twenty years of its existence. Bishop Lawrence, the first speaker, emphasized particularly its service in the education of mothers and the training of nurses in the care of infants. The second speaker, President Eliot, referred to the reduction of infant mortality by diffusion of the knowledge of methods of feeding with percentage modification of milk.

The principal address was made by Dr. John Collins Warren, who described the steps already taken towards the establishment of a new medical center in this city around the Harvard Medical and Dental schools. The Infants' Hospital, he pointed out, "is not only a place where infants are to be nursed and cured, but is to be dedicated also to the study of the many delicate and serious problems of early life." The service of such an institution to the community is not solely in the saving of individual life and the alleviation of suffering, but in the solution of such problems

and in the training of physicians to continue that study and service. To establish and assure permanence to the future of this great work is the purpose of those now interested in the welfare of the Infants' Hospital.

The plans of the new building for the hospital were exhibited and described by the architect, Mr. Arthur E. French. The exterior of the building is now essentially completed. To finish the interior and equip the hospital for work in its new quarters a further sum of $120,000 is needed. The gift of this amount should come not from the lavish generosity of a few individuals, but from the ready gratitude of many for the work already done by the institution and for the privilege of helping to establish it in larger and fuller opportunity for service in the future.

## USE OF SACCHARINE IN FOODSTUFFS.

Report from Washington, D. C., states that the pure food board of the United States Department of Agriculture has recently declared that saccharine impairs the digestion and is not a fit constituent of food-products. Its use in foods is, therefore, held to be contrary to the pure food and drug law and is to be prohibited after July 1, 1912. Saccharine, or benzoyl-sulphimide, a coal-tar derivative, with the formula $C_6H_4SO_2.CONH$, is a light, white, slightly soluble, odorless, crystalline solid, about five hundred times as sweet as cane sugar. It was discovered by Dr. Ira Remsen, of Baltimore, Md. In medicine it has been used extensively as a dietetic substitute for sugar in glycosuria, apparently without harmful results. Riegler[1] states that in the stomach it delays the proteolysis of gastric juice; and Bornstein[2] believes that its prolonged use often leads to digestive disorders. Its use in foodstuffs has been for its antiseptic properties as well as for sugar substitution. The manufacturers have already protested against the action of the Department of Agriculture in forbidding its further employment for this purpose.

## MEDICAL NOTES.

Diphtheria at University of Minnesota. — Report states that diphtheria is at present prevalent at the University of Minnesota. A number of students and several professors are said to have been sent to hospital with the disease.

Honorary Degree for Dr. Gorgas. — At the annual commencement of Tulane University, on May 17, the honorary degree of LL.D. was conferred on Col. William Gorgas, U. S. A., chief of the United States sanitary forces in the Isthmian Canal Zone.

A Tall Woman from Missouri. — Report from Chicago states that there is resident at Gorin, Mo., a woman by the name of Ella K. Ewing who is said to be 9 ft. 1½ in. in height and to weight 385 pounds. She is believed to be the tallest person in the world.

New York Homeopathic Medical Alumni. — The annual meeting of the Alumni Association of the New York Homeopathic Medical College is being held in New York City this week. The commencement exercises took place on Wednesday, May 31; and on June 1 there are to be clinics, addresses and in the evening a dinner.

Changes in Professorships at University of Pennsylvania. — It is reported from Philadelphia that Dr. Richard M. Pearce, formerly professor of pathology at the University of Pennsylvania, has been transferred to the chair of experimental pathology in that institution; and that Dr. Allen J. Smith, formerly professor of tropical medicine, has been transferred to the chair of pathology.

Death of Danish Prince. — Report from Copenhagen states that on May 27, Prince John, of Denmark, died of pneumonia in the Castle of Elsinore, at the age of eighty-five years. The Danish royal family has of late shown greater longevity among its members than in the days of Hamlet.

The Alexander Agassiz Gold Medal. — It is announced that Sir John Murray, the eminent British scientist, has recently presented to the American National Academy of Sciences a fund of $6,000 for the establishment of the Alexander Agassiz Gold Medal, to be awarded annually for the best original contribution to the science of oceanography.

Notification of Births in Belfast. — In Belfast, Ireland, an ordinance of the local board of health requires notification of every birth to be made separately by the father as well as by the physician or midwife in charge, the two reports acting as check on each other. This notification must be given within six hours after the birth, and the penalty for failure to comply with the regulation is a fine of twenty shillings.

[1] Arch. für exp. Path. u. Phar., xxv, p. 306.
[2] Zeitschr. für klin. Med., xl, p. 208.

OFFICERS OF AMERICAN DERMATOLOGICAL ASSOCIATION. — At the thirty-fifth annual meeting of the American Dermatological Association, held at the Hotel Lenox, Boston, Mass., May 25, 26 and 27, 1911, the following officers were elected for the ensuing year: President, Dr. Grover William Wende, of Buffalo; vice-president, Dr. James Sullivan Howe, of Boston; secretary and treasurer, Dr. James MacFarlane Winfield, of Brooklyn; councillor-at-large, Dr. William Allen Pusey, of Chicago. St. Louis was selected as the next place of meeting.

SUSPECTED CASE OF SMALLPOX AT MONTREAL. — It is reported from Montreal, Canada, that on May 21 the steamer *Gothland*, with two hundred and twenty-eight Scandinavian and German immigrants aboard, was detained at the Grosse Isle quarantine station of that port on account of a suspected case of smallpox in the steerage. After thorough fumigation, however, the vessel has since been allowed to proceed to Quebec.

REQUESTED APPROPRIATIONS FOR CONSUMPTIVES' HOSPITALS. — It is reported from New York that the State Charities Aid Association and the Committee on the Prevention of Tuberculosis have recommended this year an appropriation of $1,149,200 for the completion of the Sea View Hospital for Consumptives, in addition to the large regular appropriation made by the city for the care of tuberculous patients. In this connection, it is interesting to note, by way of comparison, that the amount appropriated this year by the Commonwealth of Massachusetts for the maintenance of its four existing state sanatoria is $326,814.12, but that the governor has refused to approve a requested special appropriation of $30,000. In Boston an additional appropriation of $130,000 has been asked for the construction, at Mattapan, of a new hospital building and children's ward for tuberculosis.

## BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, May 23, 1911, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 37, scarlatina 31, typhoid fever 5, measles 176, smallpox 0, tuberculosis 53.

The death-rate of the reported deaths for the week ending May 23, 1911, was 18.09.

BOSTON MORTALITY STATISTICS. — The total number of deaths reported to the Board of Health for the week ending Saturday, noon, May 27, 1911, was 238, against 215 the corresponding week of last year, showing an increase of 23 deaths, and making the death-rate for the week, 18.01. Of this number 120 were males and 118 were females; 229 were white and 9 colored; 156 were born in the United States, 80 in foreign countries and 2 unknown; 64 were of American parentage, 142 of foreign parentage and 32 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 42 cases and 1 death; scarlatina, 56 cases and 1 death; typhoid fever, 6 cases and 2 deaths; measles, 171 cases and 2 deaths; tuberculosis, 48 cases and 24 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 36, whooping cough 1, heart disease 27, bronchitis 0. There were 16 deaths from violent causes. The number of children who died under one year was 38; the number under five years, 63. The number of persons who died over sixty years of age was 69. The deaths in hospitals and public institutions were 93.

ANNUAL MEETING OF THE MASSACHUSETTS MEDICAL SOCIETY. — At the coming meeting of The Massachusetts Medical Society several changes in the usual program have been made which it is hoped will make the meeting more successful than ever. The Harvard Medical School is an ideal place for the meeting, having large amphitheaters in close connection with laboratories, in which demonstrations will be given immediately after the section meetings, illustrating the papers when possible. This will be especially valuable after the symposiums on syphilis and circulatory diseases, as it makes it possible to demonstrate the Wassermann reaction, the treponema pallida, blood-pressure apparatus, etc.

The quadrangle at the school makes a pleasant meeting place for the members.

The tea and demonstrations to which the Society is invited at Tufts Medical School by the faculty will give members an opportunity to inspect those buildings.

The attempt has been made this year to center the exercises at the medical schools, but for those wishing to see clinical work, attractive programs have been arranged at the Boston City and Massachusetts General hospitals on Tuesday morning beginning at ten.

SIXTIETH ANNIVERSARY OF THE PLYMOUTH DISTRICT MEDICAL SOCIETY. — The Plymouth

District Medical Society celebrated the sixtieth anniversary of its first meeting on Saturday, May 27. It was an interesting and instructive occasion. The meeting was held in the building of the Masonic fraternity, as nearly as possible on the site of the first meeting. An excellent exhibit of medical souvenirs of former days had been gathered together. A dinner was served to sixty members and invited guests, after which the literary exercises of the day followed. There was an address of introduction and welcome by the president of the District Society, Dr. Wallace C. Keith, of Brockton; an address of greetings and congratulation by Dr. George B. Shattuck, president of the State Society; an historical address by the Society's historian, Dr. Gilman Osgood, of Rockland; and an address on the "Surgery of 1911 and the Surgery of 1851" by Dr. Maurice H. Richardson, Moseley Professor of Surgery in the Harvard Medical School. After the exercises a handsome commemorative volume, judiciously and industriously compiled by Dr. Gilman Osgood, was distributed to those present. Dr. Osgood states in the introduction that "the object of this book is not so much to preserve records of the exercises of the day as it is to revive memories of doctors of the past, and preserve biographies of those of the present, all of whom have practiced medicine in the Plymouth district, which is rich in material relating to the history of medicine in New England."

Mount Sinai Hospital Society. — The annual meeting of the Mount Sinai Hospital Society was held in Boston last week. Particular appeal was made for contributions to the fund for the erection of a new Jewish hospital in this city.

Scarlet Fever at Wellesley. — It is reported that four cases of scarlet fever have recently occurred among students at Wellesley College. The cases have been promptly isolated and no general epidemic of the infection is expected.

Address by Dr. Cannon at Yale. — It is announced that at the coming commencement exercises of the Yale Medical School, the annual address to the graduating class will be given by Dr. Walter B. Cannon, of Boston, professor of physiology at the Harvard Medical School.

Nurses' Graduation at New England Hospital. — The annual graduation exercises of the nurses' training school were held last week at the New England Hospital for Women and Children, Roxbury. The principal address was made by Dr. Robert W. Lovett, of Boston, and diplomas were given to thirteen pupils.

Care of Rhode Island Leper by Massachusetts. — In the issue of the Journal for May 18 we noted the refusal of the Massachusetts State Board of Charity to receive at Penikese Island the leper recently discovered at Pawtucket, R. I. The Governor of Rhode Island has now made request for special legislation by Massachusetts to permit this patient to be cared for at the leper colony, but it is not known whether this petition will be favorably considered.

Committee Report on Two Hospital Bills. — The committee on public charitable institutions of the Massachusetts House of Representatives has reported favorably a bill "requiring every city and town to establish and constantly maintain one or more isolation hospitals for the reception of persons having diseases dangerous to the public health. Failure to comply with this bill is made punishable by a fine of $500." The committee has reported adversely on a bill "providing for the establishment of a homeopathic sanatorium for tubercular patients."

Continuance of the Drought in Massachusetts. — The drought in Massachusetts, to which we made editorial reference in last week's issue of the Journal, was little relieved by the somewhat scanty rain of the past ten days. Report from various cities indicates impending likelihood of a water famine. At Worcester, the city reservoirs contain only half their full capacity. At Salem and Beverly, which both obtain their water supply from Wenham Lake, there is already a marked shortage. In these and in other towns there will be distinct hardship for want of water this summer unless the situation is relieved by early and profuse rains.

Two Recent Boston Appointments. — In the issue of the Journal for May 18 we noted the nomination of Dr. Patrick Henry Mullowney to be a member of the Boston Board of Health. This appointment has been confirmed by the Civil Service Commission.

It is also announced that the Boston Board of Health has appointed Dr. John McLeod Martin, of Dorchester, to the position of school physician recently left vacant by the resignation of Dr. John L. Ames. Dr. Martin, who received the degree of M.D. from McGill University in 1889,

is professor of nervous diseases at the College of Physicians and Surgeons, Boston. He is a member of the American Medical Association and a Fellow of The Massachusetts Medical Society.

## NEW YORK.

MORTALITY STATISTICS. — The death-rate in the city for the first quarter of 1911 is announced to have been 17, as against 17.45 in the corresponding quarter of 1910, and an average rate of 18.33 for the first three months of the past five years. There was an increased number of deaths among old people, but a falling off in infant mortality, and while the mortality from organic heart diseases increased, that from tuberculosis, pneumonia and Bright's disease declined.

A CENTENARIAN. — Mrs. Hannah Van Tassel, of Cold Springs on the Hudson, who celebrated her supposed one hundred and first birthday in January last, died on May 20, after a short illness. She was married in 1828, the year the first railroad in the United States was built, but only three of eleven children she has had are still living. Her oldest son is now eighty-one.

"DONATION DAY," ST. JOHN'S HOSPITAL. — At St. John's Hospital, Long Island City, the largest hospital in the Borough of Queens, there is an annual "donation day." This year it was held on May 21, and at a public meeting in the chapel the work and needs of the institution were set forth by Dr. James J. Walsh, dean of the medical school of Fordham University. The donations were the largest ever made since this custom was started, several thousand dollars in money and supplies being received.

A NEW USE FOR QUININE. — According to the newspapers, a new use has been discovered for quinine. It occurred to a certain housewife in East Orange, N. J., that because quinine had benefited her husband, a sufferer from malaria, it might perhaps be good for a favorite hen which was ailing. Accordingly, she administered a two-grain pill, and before long was gratified to find her patient the liveliest Leghorn in the yard. The next day the hen not only laid her accustomed morning egg, but a second one in the afternoon; and since then, we are assured, she gets a quinine pill every morning and regularly lays two eggs a day.

OPENING OF PUBLIC MILK STATIONS. — On May 22 twenty-seven milk stations were opened in different parts of the city by the Committee for the Reduction of Infant Mortality, and the occasion was marked by public exercises at Seward Park, on the lower East Side, where one of the stations is located. Music was furnished by a band of forty-five boys from the Mott Street public school, and Dr. Godfrey R. Pisek, of the Babies' Ward of the Post-Graduate Hospital, who is chairman of the committee, presided. Among the speakers were Bishop David H. Greer and Commissioner of Health Lederle, who complimented the committee highly on its work. In his remarks Dr. Pisek stated that a record would be kept of all cases, and if at the end of six months it could be shown that in the districts where the stations were located infant mortality had been materially reduced, the city, which this season is maintaining a limited number of milk stations, under the direction of the Health Department, would be asked to take charge of the entire work in the future. Thirty-three additional stations are to be opened by the committee this summer, making sixty in all. Each of the stations is in charge of a matron and has an attending physician and a nurse who visits the mothers and babies in the district.

TRAITS OF THE CRIMINAL INSANE. — Dr. Richard R. Daly, of Atlanta, Ga., formerly an assistant physician at the State Hospital for Insane Criminals, has published in a New York paper some interesting comments on the recently divulged assassination plot among the inmates of that institution, upon which we commented editorially in last week's issue of the JOURNAL. One of the characteristics, he says, of the criminal insane, in which they differ very markedly from the ordinary insane, is in this faculty or habit of combination. In their sane life these men are in the habit of forming combinations to do their work, as the various gangs of pickpockets will show. They are always on the lookout for traitors, sometimes wreaking a fearful vengeance on one of their number who betrays them or is suspected of doing so. This habit of thought and life is fundamental and follows them to asylums and jails, though they are well aware that greater temptation for betrayal exists in these institutions than in free life. They fear this more than they do the delusions of the insane. "However," Dr. Daly goes on to say, "the combinations that I have been familiar with, and I saw many, of varying importance, during my time of study at Matteawan, were not made among men who had bizarre delusions. The paranoiac without grandiose ideas, the habitual criminal, the slightly demented one who would follow directions, and the malingerer made up

the group. They were dangerous, and the history of the hospital would show even worse combinations than this last one discovered."

Hospital for Deformities and Joint Diseases. — In the fourth annual report of the Hospital for Deformities and Joint Diseases, a Harlem institution which is located on Madison Avenue just opposite Mount Morris Park, it is stated that, in order to meet the demands made upon its work, the management had purchased the adjoining building, with funds generously furnished by patrons of the hospital. Notwithstanding the interruptions occasioned by the necessary alterations, the clinics were continued, and during the year there was an increase over the preceding year of 470 cases and 8,311 treatments. Twelve beds were added, making a total of 56, and the increased accommodations afforded by the new building have materially relieved the congestion which had previously hampered the hospital and dispensary work. The two buildings have been converted into an English basement, with large balconies running the entire length of the buildings on two floors, thus providing the most perfect fire protection, and, in addition, a means of keeping the patients in the fresh air and sunshine a greater part of the day. There are now over 4,000 square feet devoted to dispensary space, which includes rooms for adult male and female patients, a physical culture room, a Zander room, a large room for massage and electricity for cases of infantile paralysis, five small rooms for the application of plaster casts, and a separate x-ray room for dispensary cases. Although the classes of acute and chronic joint diseases have progressively increased, the greatest field of usefulness of the institution has been in treating disabilities resulting from the epidemics of poliomyelitis in 1907 and the following years. From 50 to 75 sufferers daily have received massage, electricity and muscle education. The benefit derived from the treatment in cases that have existed for one, two or three years has been a matter of pleasant surprise, it is stated, to the attending and consulting staff, as well as to many physicians who have visited the clinics.

3. Reilly makes some interesting observations on the prognosis of lobar pneumonia. In general, he says, it depends on the character of the soil and the virulence of the infection. In addition, there is the consideration that a vital organ is involved. In the epidemic form the infection is very virulent. Pneumonia contracted from another person is highly fatal and when it is contracted by many persons simultaneously, as in a barracks or school, the mortality averages as high as 75%. The earlier in such an epidemic a given case occurs, the worse the prognosis. But, epidemics aside, the most important factor in prognosis is the character of the soil, the age, habits, family history, the condition of the heart and kidneys. The best guide is the behavior of the heart. Any change in the pulse except a slowing is a danger signal. Arrhythmia is especially serious. The character of the pulmonic second sound is a very important index of the patient's condition. [L. D. C.]

1. Schamberg states that inflammation of the optic, auditory, facial and other cranial nerves has developed in a minute percentage of cases after the use of salvarsan in syphilis. The same complications may occur spontaneously in syphilis or after mercury. These inflammations have occurred almost exclusively in cases of recent syphilis. They appear to have occurred exclusively after the intramuscular and subcutaneous injections and not after intravenous administration. Optic and auditory neuritis have in many instances cleared up under a second dose of salvarsan or under mercury or iodides.

4. Class considers that most practitioners err in starting sedative treatment too early in the cough of phthisis. In nearly every case the morning clearing up process is beneficial. Retching is often due to excessive pharyngeal mucus and may be relieved by a simple gargle. A long uvula is often a prime offender. The cough which occurs after eating can be controlled by the smaller, more frequent meal which produces less reflex stomach activity. Cough palliatives are only allowable when the violence and frequency of the cough causes fatigue and prevents sleep.

15. Wright and Kinnicutt describe their new method for counting blood platelets and make the following interesting observations. The general average of platelets per cubic millimeter is about 297,000. In secondary anemia the count is generally high, sometimes as high as 1,130,000, while in pernicious anemia it is always low at some period of the disease. The authors suggest that the platelet count may be of value in distinguishing between the two forms of anemia in doubtful cases. In typhoid fever in the beginning of the disease the platelet count is normal or below normal, but as the disease progresses, their number increases and in convalescence may be very high. In lobar pneumonia during the progress of the disease the count may be low or normal, but at or soon after the crisis it rises very rapidly and reaches a very high point. The results of the authors' observations show that variations in the number of platelets and the number of leucocytes have no constant relation to each other. This is a further evidence that the blood platelets are not derived from the leucocytes, as some writers have believed. [E. H. R.]

12. MALLORY. *Chronic Passive Congestion of the Liver.*
13. MALLORY. *Giant-Cell Sarcoma.*

3. Through the use of dilute solutions of the bichloride of mercury, Rettger and Sherrick isolated a strain of highly resistant staphylococcus aureus. This appears as a striking instance of bacterial variation. The weaker strains are killed by the weaker solutions of the disinfectant and the number of strains is shown by a determination of the number of colonies, which decrease as the solution strength increases. Other better-known examples of variation are cited.

4. Riggs has collected sweat from individuals in health and disease by means of a rubber bag, in which the subject is inclosed. A long series of observations shows the constancy of the organic and inorganic content. The high nitrogen output and the low total solids in three nephritic experiments are of especial interest. A further study of such cases is of great importance.

8. Larrabee fails to substantiate the findings of Carnot, who describes in the blood serum of animals suffering from anemia, from hemorrhage, a hemopoietic body, the injection of which causes a marked increase of erythrocytes, even in normal subjects. The author's experiments, upon both animals and man, failed to show any such effect. [L. H. S.]

7. BELL, W. B. *Primary Abdominal Pregnancy in a Rabbit.*

1. Meisenbach states that the sacro-iliac is a true joint and admits some motion normally. It may be subject to strain or complete subluxation as well as to the diseases which affect other joints. The pelvic girdle is the main support of the trunk and when relaxed either by disease or physiological processes may jeopardize the sacro-iliac joint, causing a loose sacrum or an actual subluxation of the joint. Many of the sciaticas are due to a slipping of the sacro-iliac joint and many of the backaches, especially in women, are caused by sacro-iliac strain. Faulty attitude and flat foot in young and old are predisposing factors.

3. Lynch, studying 103 primiparæ and 82 multiparæ, found the average of the pulse in multiparæ was twice as apt to be slower in the puerperium than to remain at its previous level. In primiparæ it was likely to remain unchanged.

4. Frank and Heimann, experimenting with the complement-fixation test in eclamptic women, fail to find evidence to confirm Fieux and Mauriac, who claim to have discovered in this test a demonstration of a placental toxin and a diagnostic test of pregnancy, and think the test argues against the placental origin of eclampsia.

5. Goodall and Conn conclude that the relation between the female generative organs and the thyroid is very intimate, especially the ovaries and in them the secretions of the interstitial cells. The uterus is devoid of any influence on thyroid activity except in that its function may affect the ovarian function and through this the thyroid. Thyroid activity is in a measure under the governance of ovarian activity. Ovarian hyperactivity is often a cause of the development of exophthalmic goiter. Diminished or absent ovarian activity usually coincides with myxedema. Puberty, menstruation, pregnancy, lactation and menopause exercise a profound influence upon thyroid secretion. Thyroid and ovarian secretion do not supplant, but neutralize each other. [E. H. R.]

9. Gillespie, E. *A Case of Acute Hemorrhagic Pancreatitis; Operation; Recovery.*
10. Rae, J. *An Unusual Case of Pericardial Effusion.*

1. Hertz, in the first of the Goulstonian Lectures, considers the sensibility of the alimentary tract under the following headings: (1) Tactile sensibility. (2) Thermal sensibility. (3) Sensation produced by chemical stimulation. (4) The sensation of fullness and distention.

7. Stoney reports the details of a case of ascites due to chronic fibrous peritonitis, with hepatic cirrhosis, treated by lymphangioplasty with marked benefit. [J. B. H.]

### April 29, 1911.

1. *Tuck, G. L. *Inaugural Address on Plague.*
2. *Hertz, A. F. *Goulstonian Lectures on the Sensibility of the Alimentary Canal in Health and Disease. Lecture II.*
3. *Dawson, B. *The Microbic Factor in Gastro-Intestinal Disease and Its Treatment.*
4. *Chapple, H. *A Consideration of Some Cases of Advanced Tubercular Joints Treated by Ileo-Colostomy.*
5. Stratford, E. P. *A Case of Lymphadenoma in a Woman Aged Sixty-Three Years.*
6. Martin, L. C. *Two Interesting Cases of Acute Intussusception and Appendicitis.*
7. Gray, G. D. *A Report on the Septicemic and Pneumonic Plague Outbreak in Manchuria and North China (Autumn, 1910.–Spring, 1911).*

1. Tuck describes interestingly the recent plague epidemic in China, dwelling on its relation to the marmot as a spreader of the disease, the progress of the epidemic and the methods of quarantine and disposal of the dead.

2. In the second of the Goulstonian Lectures on the sensibility of the intestinal tract, Hertz dwells on the sensation of fullness and distention, the sensation of emptiness and hunger and pain.

3. Dawson believes that in various chronic disorders of the gastro-intestinal tract there is an actual infection of the mucosa by various bacterial organisms just as there is in cystitis and bronchitis. He describes his experiments on this subject, the results of his investigations and the relation of hydrochloric acid to the growth of bacteria. He discusses the relationship between appendicitis, colitis and infections of the biliary tract and gastric disturbances. He mentions the well-known bearing of carious teeth on gastric disorders. He gives the details of several cases of chronic gastric disorders in which the patient was treated with an autogenous vaccine obtained from a growth from the stomach contents with beneficial results.

4. Chapple believes that constipation and the attendant auto-intoxication is a large factor in the resistance to treatment of many tuberculous joints. Accordingly, he has performed an iliocolostomy on such patients, following the lead of Lane. He gives the details of eight cases each under twelve years, in which marked benefit to the joint condition followed this operation. [J. B. H.]

13. COWEN, I. *A Case of Retained Menses.*
14. COTTON, W. *The Fluoroscopic Diagnosis of Direction by a Plane Mirror upon the Screen.*

1. Powell, in a short paper, briefly discusses mediastinal growths in general and presents two illustrative cases.

2. Clarke discusses five cases of movable kidney, each of which presented some obscure and unusual symptoms and especially symptoms which led to the suspicion of gall bladder or pyloric trouble.

5. Corner, in an article illustrated with numerous diagrams and photographs, discusses the various methods of gastrostomy. The unsatisfactory results so often met with are, in his opinion, due to (1) inanition and exhaustion of the patient, and (2) an imperfect method of operation. He discusses and describes the various valve operations as practiced to-day and gives the details of a method of his own, with results and illustrative cases.

6. Walker discusses at length the various forms of pyelitis and suppurative nephritis as to nomenclature, clinical features, prodromal symptoms, after-history and pathology. He goes at length into the question as to whether or not an ascending infection is possible and compares it with hematogenous infection and discusses briefly treatment.

9. Williamson believes that in guipsine, a drug obtained from mistletoe, the physician possesses an effective and safe remedy for the treatment of cases of supernormal arterial pressure. He describes an elaborate series of investigations on the use of this drug. The guipsine pills (5 cgm. each) were given in amounts varying from six to twenty-five in the twenty-four hours.

10. Hernaman-Johnson discusses in a general way the various methods now in vogue of treating mucous colitis. [J. B. H.]

## EDINBURGH MEDICAL JOURNAL.

3. BEARD, J. *Outbreak of Typhus Fever in the City of Carlisle.*
4. SMITH, G. M. C. *Heredity as a Causative Factor in Disease.*

1. Wilkie, in an excellent article admirably illustrated, discusses at length retrograde venous embolism and its relation to gastric ulcer. He summarizes his investigation as follows: (1) Thrombosis of omental veins is readily produced by mechanical, thermal and bacterial agencies. (2) From thrombosed omental veins emboli may frequently separate, probably owing to the periodic vasodilation and contraction of these veins associated with the ingestion of food. (3) Emboli from omental veins may, under certain circumstances, be carried by gastric veins and become impacted in the venous plexus of the submucous coat of the stomach and form a gastric ulcer. He further goes on to suggest that: (1) The hematemesis sometimes met with in cases of acute appendicitis is due to an acute gastric ulcer resulting from blockage of a gastric vein by a septic embolus from a thrombosed omental vein. (2) On similar lines the omental vessels may form the connecting link in the association of chronic gastric or duodenal ulcer with an inflammatory process in the lower abdomen. (3) The same theory may possibly explain some cases of acute pancreatitis brought about by septic emboli from an inflamed omentum. [J. B. H.]

8. *FRAENKEL, M. *The Röntgen Rays in Gynecology.*
9. KATZ. *The Operative Contract.*

6. The author, believing that the cause of pyelitis gravidarum being a tipping to one side of the pregnant uterus, causing pressure on, and a consequent backing up in, the ureters and so to the kidney, recommends that the patient be made to lie as much as possible on the opposite side, the intention of course being to remove the pressure from the ureter. This, combined with simple urinary antiseptics, he has found to work well in a number of cases of pyelitis of pregnancy. He cites cases of other men, as well as his own, to prove his contention.

8. The author has collected from the literature (mainly German), reports of series of cases, such as fibroids of the uterus, dysmenorrhea, menorrhagia, metrorrhagia, various sexual neurasthenias, and also a series of inoperable carcinomas of the uterus, which have been treated by means of the x-ray. The reports are all enthusiastic, and the author makes great claims, especially for fibroids, which are said to melt away with amazing rapidity. He claims that no damage is done the ovaries if the dosage is regulated carefully, citing animal experimentation as well as clinical results to show this. He ends his paper with the remark that there is a tremendous future for the x-ray in gynecology. [J. B. S., JR.]

## DEUTSCHE ZEITSCHRIFT FÜR CHIRURGIE. BD. 109.

### HEFT. 3–4. APRIL, 1911.

1. LEVY, R. *Contributions to the Question of Coxitis, Coxa Vara and So-Called Osteo-Arthritis Deformans Juvenilis.*
2. *PLESSNER, M. *Villous Cancer of the Thyroid Gland.*
3. EXNER, A. *The Knowledge of the Etiology of Inflammatory Rectal Stenoses.*
4. *SCHLEINZER, J. *Lymphosarcoma of the Tongue: A Contribution to the Permanent Cure of Lymphosarcoma.*
5. ARZT, L. *The Knowledge of Dermoid Tumors of the Pelvic Connective Tissue.*
6. *HARTEL, F. *Gastro-Enterostomy in the Röntgen-Ray Picture.*
7. DOEPFNER, K. *Contributions to the Knowledge of Meckel's Diverticulum.*

8. Karewski. *Brief Remarks on the Paper of L. Heidenhain on "The Covering in of Large Defects of the Skin following Extensive Breast Amputations."*
9. Thöle. *Volvulus after Eventration and Reposition of the Bowel under Opium.*
10. Thöle. *Peritonitis of Idiopathic Origin.*

2. The author reviews the literature on the subject of cancer of the thyroid, remarking on the infrequency of the cases reported. He then gives a careful summary of Langhans' classification of malignant tumors of the thyroid (seven in number). Following this he reports at great length a case of his own of papillary cyst adenoma of the thyroid, accompanied by three excellent microphotographs of the tumor, and from the literature he selects other cases, similar to his own. He thinks that these cases which Langhans grouped sixth in his classification simply as papillomas should receive a separate classification because of their extremely malignant tendency to recur, and to metastasize both through the blood and the lymph streams. He does not think that Langhans considers sufficiently the malignant tendency when simply grouped under "papillomas."

4. The author reviews the literature of this extremely rare form of sarcoma, and reports a case of his own which was operated on five years ago and has had only one small recurrence, and that about two months after the original operation. The case is now well. He analyzes a number of the cases which have been reported in the literature. The latter part of his title is somewhat misleading, as he has nothing to offer but free and radical excision.

6. This article is a long and careful study of twenty-two cases of gastro-enterostomy, most of which were done for ulcers of the duodenum, or for the stomach. For any one interested in the surgery of the stomach, the article is well worth reading. Each case is analyzed with the extremest care, and there is a large number of semi-diagrammatic pictures of each case, made with the x-rays, showing just exactly what is taking place from two to three hours up to one and a half years following the operation. The article is well worth while. [J. B. S., Jr.]

## Obituary.

### JOHN TATHAM THOMPSON, M.B., C.M., EDIN.

Dr. John Tatham Thompson, who died of gastric carcinoma on April 28, at Cardiff, South Wales, was born at York, England, in 1858. After graduating from University College, Bristol, he studied pharmacy for a time, but subsequently took a medical degree at the University of Edinburgh, where he was a pupil of the late Dr. Argyll Robertson. In 1887 he settled at Cardiff in the practice of ophthalmology and was almost immediately appointed ophthalmic surgeon at the Cardiff Infirmary and surgeon-oculist to the South Wales Institute for the Blind. He was an operator of great technical skill, an excellent artist and a man of energy and originality. He contributed much to the medical literature of his specialty, and became one of the foremost of the younger British ophthalmologists. He devised a modification of the usual operation for anterior staphyloma, and was one of the first to employ the electro-magnet successfully for the removal of steel fragments from the retina. He was author of "The Influence of Early School Life in Eyesight," and made valuable contributions on the pathogenesis of miner's nystagmus. The suffering of his last illness he endured with the greatest fortitude and resignation, and the regret only that he must leave his work so soon. He is survived by his widow and by four children.

## Miscellany.

### RECENT BEQUESTS IN PUBLIC MEDICAL CHARITY.

During the past week an unusually large number of bequests to public charitable and medical institutions in and about Boston has been announced.

The will of the late Samuel Hubbard Scudder, of Cambridge, Mass., who died on May 17, was filed on May 27 in the Middlesex Probate Court. It provides that on the death of a private beneficiary, the sum of $23,000 shall revert to Harvard University to be used for the benefit of the Harvard Medical School.

The will of the late Mrs. Lydia Augusta Barnard, of Milton, Mass., which was filed for probate at Dedham, Mass., last week, contains bequests of $5,000 each to the Sharon Sanatorium, to the Channing Home, Boston, and to the New England Hospital for Women and Children, Roxbury.

The will of the late J. Francis Loring, of Arlington, Mass., who died on May 14, was filed last week for probate in the Middlesex Probate Court at East Cambridge, Mass. It contains a bequest of $100 to the New England Baptist Hospital.

The will of the late James Farrell, of Boston, who died on May 18, was filed for probate in this city last week. It contains bequests of $500 each to the Carney Hospital, South Boston; to St. Elizabeth's Hospital, Boston; to the Holy Ghost Hospital for Incurables, Cambridge, Mass., and to St. Mary's Infant Asylum, Dorchester.

The will of the late Mrs. Henry R. Shaw, of Boston, who died on May 21, was filed for probate last week. It provides that, in the event of the intestate death of the principal beneficiary before the age of twenty-five years, one sixth of the residuary estate shall revert to the Industrial School for Crippled and Deformed Children, Boston.

The will of the late Mrs. Josiah Parsons Cooke, who died at Cambridge, Mass., on May 21, was filed for probate at East Cambridge on May 24. It contains an immediate bequest of $5,000 to the Cambridge Hospital, for the endowment of a free bed in the women's ward, in memory of the testatrix's father, the late Dr. Elisha Huntington, of Lowell, Mass. It further provides that on the death or remarriage of a beneficiary, a further sum of $5,000 shall revert to the same institution.

These legacies are examples of the manner in which the permanent endowment of worthy medical charity is gradually established in our community by the generosity of private individuals.

### ANTITYPHOID VACCINATION FOR BENEFICIARIES OF PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE.

In the weekly report of the United States Public Health and Marine-Hospital Service for May 19 is announced the offer of free antityphoid vaccination to all beneficiaries of the service. These include persons employed on board in the

care, preservation or navigation of any registered, enrolled or licensed vessel of the United States, the officers and crews of the Revenue Cutter Service, and of the Lighthouse Establishment, seamen employed on the vessels of the Mississippi River Commission and of the Engineer Corps of the Army, keepers and crews of the United States Life-Saving Service, and officers and seamen on vessels of the Coast and Geodetic Survey. The circular letter of instruction, which contains this announcement, states that "although the taking of the treatment will be voluntary, some beneficiaries will undoubtedly take advantage of this offer, and by so doing protect not only the traveling public which they serve, but the general public whose water supplies they are liable to infect."

## ARMY MEDICAL CORPS EXAMINATIONS.

THE Surgeon-General of the army announces that preliminary examinations for the appointment of first lieutenants in the Army Medical Corps will be held on July 10, 1911, and Sept. 5, 1911, at points to be hereafter designated.

Full information concerning these examinations can be procured upon application to the "Surgeon-General, U. S. Army, Washington, D. C." The essential requirements to securing an invitation are that the applicant shall be a citizen of the United States, shall be between twenty-two and thirty years of age, a graduate of a medical school legally authorized to confer the degree of doctor of medicine, shall be of good moral character and habits, and shall have had at least one year's hospital training after graduation.

In order to perfect all necessary arrangements for the examination, applications must be complete and in possession of the Adjutant-General at least three weeks before the date of examinations. Early attention is, therefore, enjoined upon all intending applicants. There are at present sixty-one vacancies in the Medical Corps of the Army.

## Correspondence.

### USE OF THE INCUBATOR IN STUDY OF EMBRYOLOGY.

BOSTON, May 26, 1911.

*Mr. Editor:* That the study of embryology by the use of the incubator is of no modern date is evident from the quotation given below from a work by the famous Sir Kenelm Digby, entitled, "*Two Treatises: In the one of which The Nature of Bodies In the other The Nature of Man's Soul is looked into In way of Discovery of the Immortality of Reasonable Souls, London, MDCLXV.*" The first edition was published in Paris in 1644. The work is a bulky volume, 429 pages being devoted to the body and 144 pages to the soul.

The quotation referred to is as follows: "Sir John Heydon (that generous and knowing gentleman, and consummate souldier, both in theory and practice) was the first that instructed me how to do this, by means of a furnace so made as to imitate the warmth of a sitting hen. In which you lay several eggs to hatch: and by breaking them at several ages, you may distinctly observe every hourly mutation in them, if you please."

Very truly yours,

CHARLES G. CUMSTON, M.D.

## RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, MAY 20, 1911.

| CITIES. | Reported deaths in each. | Deaths under five years. | CITIES. | Reported deaths in each. | Deaths under five years. |

## SOCIETY NOTICES.

RHODE ISLAND MEDICAL SOCIETY. — The annual meeting is to be held at four o'clock P.M., Thursday, June 1, 1911, in the State Normal School Building, Providence, R. I.

SECRETARY OF AMERICAN SURGICAL ASSOCIATION. — The Secretary of the American Surgical Association is Dr. Robert G. Le Conte, of Philadelphia.

## RECENT DEATHS.

WILLIAM PERRY HAGER, M.D., M.M.S.S., died at Northampton, May 18, 1911, aged thirty-six years.

DR. E. ARTHUR DAKIN, who died last week at Gloucester, Mass., was born in Lower Argyle, N. S., in 1853. He was at first a pharmacist, but subsequently practiced medicine for a number of years at Magnolia, Mass.

DR. ALBERT H. HAYES, of Boston, died suddenly in this city on May 22. He was born in 1837 at Alton, N. H.

DR. HENRY C. PRENTISS, of Somerville, Mass., died in that city on May 26, at the age of ninety-seven years.

## BOOKS AND PAMPHLETS RECEIVED.

Treasury Department, Public Health Bulletin No. 43. I. Studies upon Plague in Ground Squirrels. II. A Plague-Like Disease of Rodents. By George W. McCoy.

Galvanotropic Orientation in Gonium Pectorale. By A. R. Moore and T. H. Goodspeed. University of California Publications in Physiology.

On a Possible Source of the Biological Individuality of the Tissues and Tissue-Fluids of Animal Species. By T. Brailsford Robertson. University of California Publications in Physiology.

# THE CLASSIFICATION OF DIABETES MELLITUS.

BY A. E. AUSTIN, M.D.,

*Physician to Mount Sinai Hospital and Director of its Clinical Chemistry Laboratory.*

A HOST of difficulties has been presented to the clinician in gauging the varied severity of this disease; we see all grades from the mild form which can be controlled by merely eliminating sugar from the diet to that form in which absolute fasting does not free the urine from sugar. The reason for this is, of course, twofold; first, because each individual afflicted with this disease has a constantly varying power of utilizing or oxidizing that portion of carbohydrate which is given him, a power which even in the individual may remain constant, may vary from day to day or sometimes from hour to hour of the same day; for instance, Von Noorden has found that some patients can tolerate carbohydrates better in the afternoon and evening that in the morning on an empty stomach, while others can take the total amount allowed in one meal rather than distribute it over the period of three meals. Secondly, we have to take into account the origin of dextrose from protein food, a fact which becomes startling when we realize that while from the protein richest in carbohydrate mucin, by laboratory means we can obtain only 25 to 35%, from egg albumen 10 to 15% and from meat less than 1% of sugar, the body in its process of metabolism can produce approximately 60% of the protein ingested in the form of dextrose, according to Lusk, where carbohydrate tolerance is nil. It seems a matter of indifference to the body in such cases whether the protein is taken as food or obtained from the body itself. Another curiosity of diabetic metabolism is that while by laboratory methods it is impossible to obtain any dextrose from casein, this very protein furnishes sugar most abundantly when taken as food. It is possible and probable that the energetic means taken to split off the carbohydrate molecule from protein (cooking with strong acid) destroys the sugar thus separated, as the latter is known to be very susceptible to these agencies, as note the destruction of dextrose in the Moore test for diabetic urine where alkali is used with heat. In the body the ratio of protein ingested or metabolized to the dextrose eliminated remains usually as 62:5::3:65 in severe cases. In fact, it is sometimes found that the severest forms of diabetes tolerate a small amount of carbohydrate better than a very large amount of protein food. How, then, if carbohydrate is not performed in the protein molecule, can the body manufacture it? It seems decidedly more difficult than the transmutation of baser metals into gold. From alanin or aminopropionic acid, however, an amino-acid, one of the many final digestive products of protein, it requires only the separation of the amin body or $NH_2$ factor, which is promptly converted into urea or an organic acid ammoniate, the oxidation of the propionic acid to lactic acid, $C_3H_6O_3$, and the union of two of these latter molecules in the liver to form dextrose, $C_6H_{12}O_6$. Of course, the matter is not as simple as this would imply, but such an illustration shows how other similarly formed amino-acids may be synthesized to form glucose. As to fat, the proof is still lacking that any portion of the fat, other than the glycerine, forms sugar. This glycerine, especially in the form of the aldehyde, has been proved to be converted to sugar by Woodyat; as to the conversion of the higher acid constituents of fat, we are still in as much doubt as ever. Lusk declares that there is no proof of this conversion, while Von Noorden is inclined to believe that cases may become so severe that the individual may eliminate an amount of sugar much beyond the quantity stated by Lusk as being derived from 6.25 gm. of protein, namely, 3.65 gm. of sugar. Hence, the only source remaining must be the fatty acids, since the glycerine of the fat could not account for it; for all practical purposes, however, we we may rely upon the carbohydrates and the protein taken as food (and existing in the body) as the sources of sugar. It seemed formerly that the classification must be based upon the organ which was apparently affected; that is, mild cases of glycosuria exsaccharo must be dependent wholly upon the inability of the liver and muscles to store up more than a certain portion of the carbohydrate taken at a meal, as glycogen, and hence the excess beyond the .3 % or .1 %, as Von Noorden would have it, permissible in the blood was eliminated; on this account hepatic glycosuria was a common term, with which was also allied the glycosuria of the obese, on the theory that the liver was associated in the conversion of carbohydrates to fat and that it had failed in its function. Then we gradually traced this hepatogenous glycosuria to nervous influence and thus explained the action of brain tumors, traumatism, apoplexy and carbon monoxide poisoning in the production of glycosuria; but in every case of this character the glycosuria did not occur unless there was glycogen stored up; in other words, glycosuria could not be produced in a fasting subject by these means and in the well-fed usually ceased as soon as the stored-up animal starch was exhausted. After the discovery was made that phloridzin and possibly caffein were able to produce glycosuria, we began to hear of a renal form which arose from the lessened resistance of the renal cells to the usual sugar content of the blood; under such circumstances, in contradistinction to usual diabetes, an impoverishment of sugar in the circulating blood does occur, but it has been found in true diabetes that the renal cells by a process of adaptation offer still greater resistance to the passage of sugar than usual, so that the blood of diabetics only after prolonged continuation of the disease always contain a larger amount of sugar than the non-diabetics, therefore, a true renal diabetes does not exist. When Minkowski found by removal of the pancreas that

a prolonged and fatal diabetes occurred, we congratulated ourselves that now we had found its cause and coined the word "pancreatic diabetes"; repeated pathological examinations of the pancreas of those dying from true diabetes have shown, however, that while that organ may be diseased in many instances, it is not so invariably, so that this classification has no value clinically. The pituitary and adrenal diabetes, words signifying the possible causation of persistent glycosuria, are as yet only curiosities and have not been sufficiently investigated clinically to be granted much of a hearing; we only know that acromegaly and Addison's disease are often accompanied by glycosuria without evidence of their common cause except Herter's proof that adrenalin injected or painted upon the pancreas or even mild mechanical injury to the adrenals themselves *in vivo* may produce glycosuria. Then, if we cannot make an anatomical classification of diabetes, and we have seen how often two organs are associated in the production of glycosuria, for instance, brain and liver, and thyroid and pancreas, we must look for some common ground which exists in all forms of diabetes, and we find that in the limited ability of the organism to utilize carbohydrates; this power in all probability is never fully lost; even in these instances where apparently all the carbohydrate taken is found in the urine and much more even, from the protein food, we can only say that the nitrogen-dextrose ratio remains fairly constant, but we cannot say that the disordered organism may not produce even more than 60% of dextrose from protein and burn up a portion of it since in no way by laboratory methods can we, as stated, learn the exact amount of dextrose contained in the protein molecule, nor are we assured even in these severe cases that all the carbohydrate taken appears in the urine since its glucose is made up of these two factors, carbohydrate taken as food and dextrose obtained from protein either in the food or from the body.

Thus we must make a valuation of the diabetic as we would any damaged machine; what is its output as compared with an undamaged machine 90%, 80% or 70% or less of efficiency? As the normal human can utilize 100% of the carbohydrate taken, especially in the form of starch (sugar tolerance is omitted because so variable) we have only to deduct the urinary glucose from the absolute carbohydrate intake and compare this difference with the latter to determine the efficacy of the body as a sugar-destroying agency. If, on the contrary, all the carbohydrate taken is found in the urine, we have only to determine the nitrogen of the protein food taken, which can be easily done by reference to Atwater's tables or practically any work on dietetics; multiply this by 3.65 according to Lusk, or 4 according to German authors, and deduct from this, in case no carbohydrate has been taken, the urinary glucose. Then compare this latter difference with the total possible glucose to be derived from the protein. This percentage of efficacy to oxidize dextrose will, of course, vary in the same individual as his tolerance increases or diminishes, but will inevitably distinguish the grades in the diabetic process better than the terms "mild," "moderate" and "severe," terms whose meaning varies with the different authorities; as well use the terms "mild," "moderate" and "severe" fever, when we have the clinical thermometer before us. This method of grading diabetics enforces two things,—the weighing of the cooked food and the accurate estimation of sugar in the urine, not the percentage only, for the latter has been the source of innumerable errors in determining the progress of the disease. As the presence of sugar in the urine also stimulates the kidney to a greater elimination of water, so its diminution causes a lessened diuresis and often the latter precedes the former so that the percentage of sugar increases while the day's total is less and really the patient is improving while the percentage indicates that his condition is becoming worse. In order to illustrate this estimation of the oxidative power of diabetics, a few cases are included in this paper.

E. A. Jan. 30. Male, thirty-eight years. Weight 145 lb. No marked change in weight for several years, no thirst, no itching, not conscious of increase of urine, skin soft. Sugar was first discovered in the urine within six months in a life insurance examination. Upon being compelled to fast twenty-four hours, no sugar was found in the urine.

Feb. 12. Having been placed on a Von Noorden antidiabetic diet since the last date, with the addition of 120 gm. of bread, the urine amounted to 1500 ccm. for the day with 12 gm. of dextrose.

Feb. 23. With the same diet and 60 gm. of bread, 1060 ccm. of urine were passed with 4.24 gm. of dextrose.

March 2. Upon the same diet with the same amount of bread, 1900 ccm. of urine were passed with 2.15 gm. of dextrose.

March 5, on the same diet, a mere trace of dextrose not measurable was found. This was followed by a two weeks' stay in Bermuda, during which sea bathing was daily indulged in; after this on a return to regular diet from which sugar alone, i. e., not starch, was excluded there was not the slightest trace of sugar in the urine. Here the 120 gm. of bread containing 72 gm. of carbohydrate produced 24 gm. of urinary sugar, therefore, utilization amounted to 66%, that is, this was the amount, as compared with the total, which did not appear in the urine as there was no sugar when fasting. At the second examination 60 gm. of bread with 36 gm. of carbohydrate produced 4.24 gm. of sugar, a utilization of 88%. March 2, as can be seen, on the same diet this eliminated sugar had diminished to 2.15 gm., while 94% was utilized; for convenience sake, it is well to designate these positive utilizations with + to indicate that the protein food does not apparently share in the urinary sugar, leaving the designation — for those cases where apparently no carbohydrate of the food is oxidized and the supply comes wholly from the protein, so that in this instance we began with the utilization factor of + 66% and closed with one of + 94%, which gradually increased to + 100. In the meantime the treatment was wholly dietary with the exception of antipyrine in 0.3 gm. doses three times a day, to which I attribute but little efficacy apart from diet.

Mr. J. J. D., Nov. 2. Paternal uncle died of diabetes and a sister now has it. Afflicted for ten years. The patient has an enlarged prostate and is disturbed only by thirst and frequent micturition with sometimes involuntary passage of urine in sleep. On unrestricted diet the amount of urine was 4750 ccm. with 1.1% dextrose or 55 gm. in twenty-four hours. No diacetic acid.

Nov. 20. From last date Von Noorden carbohydrate free diet with addition of 100 gm. of bread. The day's urine amounted to 3750 ccm. with 7.5 gm. of dextrose.

Dec. 12. On the same diet 3000 ccm. urine were passed with absolutely no glucose. The only drugs were aspirin 2 gm. daily during the first period and codeine phos. 0.12 gm. daily during the second period. Here regarding the bread as containing 60% of carbohydrates we have a utilization factor of + 87.5% and apparently a very mild form of this disease, though it had existed for a long time. The removal of the sugar from the urine did not, however, proportionately reduce the volume of urine, and it had occurred to me, though in a cursory examination of the literature I could find no evidence for that view, that there may be an association between these milder forms of glycosuria and diabetes insipidus.

Mrs. G., sixty-seven years. Began to have cough two years ago for which went South. About one year ago sugar was found in the urine. At present, excessive cough, sleeplessness, no great thirst, profuse expectoration which is not offensive in odor. Dullness over upper right lung extending half way from clavicle to nipple in front, bronchial respiration, increased voice sounds and abundant moist râles over the same area. Left lung, normal respiration and resonance. Examination of sputum shows tubercle bacilli. On a strict protein-fat diet with the addition of 120 gm. of white bread for a period of two weeks the twenty-four hours amount of urine was 1600 ccm. with 16 gm. of sugar. There was no albumen, no diacetic acid and no acetone. The ammonia nitrogen by the Henrique's process was 6% of the total nitrogen. Regarding the bread as containing 60% carbohydrate, we have 72 gm. of the latter with a loss of 22% or a utilization factor of + 88%. On account of the phthisis, it was not considered advisable to reduce the carbohydrate lower in an effort to render the patient sugar-free, though both Naunyn and Umber quote cases where this was done with benefit to the phthisical process. Their patients, however, were much younger. When, as in these cases, the loss of sugar in the urine is only a small percentage of that taken in the food, it is probable that the balance is utilized either by direct oxidation or stored up as glycogen or fat and the protein constituents of either the body or the food are spared a prostitution of their uses to that of production of carbohydrate. Therefore we regard this utilization as + because, though the normal stage is not reached, yet a fairly good degree of combustion in maintained; furthermore, we see how toleration increases with rest of the sugar destroying function; in other words, "no cross, no crown." Patients must submit to deprivation of carbohydrates for a time in order to be rewarded by restoration of this class of food. This applies, of course, to plus or positive power of utilization. This classification also may correspond to the mild cases of various authors, but the degree of mildness may vary from + 1 to almost + 100% of combustion. There may be and probably are, as Von Noorden states, special idiosyncrasies in regard to the character of the carbohydrate employed, whether potato, bread, fruit or milk and also with reference to the time of the day at which it is taken, and observations of such individual peculiarities are very properly the function of sanatoria and hospitals, but for home treatment certain definite rules of diet, as simple as possible, must be adhered to and too many variations confuse the patient and the attendant, while the established diet of Von Noorden and Naunyn, especially of the latter, which offers varied ménus without starch or sugar for every day in the week, and to which a definite amount of bread or its equivalent may be added, fulfill every need. If we could regard the metabolism of the diabetic as measured by a pressure gauge where there may be either compression or a vacuum, then 0 represents the point where there is neither, so 0 in the metabolism of the diabetic represents the point where all carbohydrate taken is eliminated in the urine, or rather an amount equal to this, for, as stated, it is difficult to say whether, in such cases, a portion of the starch is utilized and the rest of the remaining sugar of the urine is made up from that of the protein; at least, if the elimination equals the ingestion, we may regard utilization as 0. This does not mean to imply that patients with such a degree of utilization may not progress to the + side, which is common, or drop to the negative side, which is rarer. This stage or grade is indicated by the fact that on a carbohydrate-free diet no sugar appears in the urine, or rather ceases to appear after a week of such restriction, for the accummulation of glycogen is bound to be discharged before the protein is called on. This second class means practically that as soon as bread is added to the antidiabetic diet in however small amounts, patients promptly respond with the elimination of sugar. These individuals can sometimes utilize fruit, milk or vegetables better than bread. In my list of personal cases no good illustration of this condition could be found, but Naunyn describes several which illustrate this state very accurately and which as far as carbohydrate utilization goes comes under the list graded as 0.

A woman thirty-four years of age sought treatment on account of great thirst and feeling of weakness; she was very anemic looking and her weight was 94.6 lb. Upon a strict antidiabetic diet, with the exception of one glass of milk daily, 3800 ccm. of urine were passed with 26 gm. of sugar. In six days, however, upon this diet the urine became sugar free and remained so when the milk was increased to 500 ccm. daily, but with one slice of bread (30 gm.) added, the patient's urine amounted to 1600 ccm. daily with 1.6 gm. glucose.

A man of fifty-three years had greatly increased hunger and thirst and moderate loss of flesh. There was a total left-sided facial paralysis without pain. Upon a diet selected according to the patient's choice 3400 ccm. of urine were passed daily with 221 gm. of glucose. In eighteen days, upon a meat and fat diet, no sugar was found in the urine. After three months of a strict antidiabetic diet 150 gm. of bread were added to the diet, whereupon there was a prompt return of sugar in the urine.

A man of thirty-three years sought relief for weakness and loss of flesh; hunger and thirst were increased; he passed urine oftener in large quantities and had cramps. With a strict antidiabetic diet to which 150 gm. of milk and 20 gm. of bread were added, he had a daily elimination of urine of 2450 ccm. with 100.4 gm. of glucose; with the removal of the bread and milk, 1200 ccm. of urine were passed which was sugar free. After months of a fat-protein diet only 40 gm. of bread could be added to the daily food without the recurrence of the sugar.

These are the cases in which such uncertainty exists with reference to their future course because, being on the border line, the tolerance

shows a tendency, though less often, to diminish as well as to increase.

Many diabetics belong to still another class which we may designate as minus, basing the severity of the disease on the steadily diminishing tolerance for starch or sugar. These are also the cases where there is a steady drain on the tissues of the individual for material for oxidation, a need which neither the protein, sugar nor starch can satisfy; they become steadily more emaciated and show most peculiarly those evidences of eminent acid intoxication,—an excessive ammonia-nitrogen factor, diacetic and oxybutyric acids in the urine. In these individuals, it is absolutely hopeless to attempt to eliminate the sugar wholly from the urine by diet or by medicine and all we can hope to do is to raise somewhat the sugar tolerance by short periods of abstinence or a very limited starch ration and then return to a fairly liberal carbohydrate portion in order to check the ever-increasing tide of acid poisoning. Here we must measure the amount of utilization of the theoretical protein sugar in the same way by the percentage of the total destroyed and not appearing in the urine. Of course it is possible that only a portion of this protein sugar undergoes this perverted metabolism, such an amount as is necessary to subserve the needs of the organism, but so wastefully used that a portion appears in the urine. It will render the matter much clearer, however, if we regard the total possible sugar as synthesized from the amino-acids in the proportion estimated by Lusk in a case where apparently all power of sugar combustion was lost. I wish to offer an illustration of this condition in the following cases:

Mrs. E. W., fifty-six years of age, one year ago suffered a severe shock from the death of her husband and serious illness of her son. She was confined to her room for three months; from that period she began to lose flesh and began to pass large quantities of urine, voiding usually once at night. Jan. 15, careful examination showed that the woman had arteriosclerosis. Upon an ordinary self-selected diet she passed 1900 ccm. of urine in a day with a sugar content of 61.9 gm. and 20.43 gm. of urea. In order to determine whether this diabetes was of pancreatic origin an examination of the stool was made, where the only abnormality found was a mass of fatty acid crystals which may come from an impaired secretion of pancreatic juice since alkali is lacking for soap formation, but may come equally as well from hastened intestinal motility; unsplit fat was not found. Jan. 19, after twenty-four hours abstinence from food, a sample of urine was found to contain 6.3% of glucose with a marked acetone reaction. Jan. 25, the patient was placed upon a strict protein-fat diet to which 120 gm. of bread (72 gm. carbohydrate) was added daily. Jan. 29, 3000 ccm. of urine were passed in the twenty-four hours with a sugar content of 120 gm. and a marked diacetic acid reaction. Unfortunately the total protein in the diet was not measured during this period, but from the sugar in the fasting urine and the excess of urinary sugar over starch intake, it is shown that the utilization is minus; in other words, sugar is being made from the amino acids, a fact also confirmed by the Gerhardt reaction. Feb. 9, on account of the evidences of acidosis, the patient was allowed 250 gm. of potato bread containing 45 gm. of carbohydrate daily as well as 120 gm. of white bread. At this time there was a marked fatty diarrhea controlled by the diet. March 8, 3000 ccm. of urine were passed containing 181.5 gm. of glucose and 42 gm. of urea and showing a strong diacetic acid reaction. Patient at this time was taking 162 gm. of protein daily and 117 gm. of carbohydrate which being deducted from the total elimination leaves 64.2 gm. to be derived from protein. Theoretically 162 gm. of protein should furnish 97.2 gm. of carbohydrate, of which that number less 64 must be utilized, or 33.2 gm., giving a utilization factor of minus 34.1%. This shows that the tolerance for both native sugar and protein sugar, is markedly diminished and the individual is providing needed oxidation material from her own tissues (loss of weight in one year from 152 lb. to 106½ lb. at present date).

April 11. The day's urine at this time amounted to 3875 ccm., with 242.2 gm. of sugar, and had a marked diacetic acid reaction; the urea was 32.6 gm. The diet had contained 142.8 gm. of protein, 120 gm. of white bread (92 gm. of carbohydrate) and 250 gm. potato bread (45 gm. carbohydrate) to which 15 gm. of levulose were added daily. Otherwise the patient was upon a strict antidiabetic diet whose caloric value was kept to the normal by means of fat. Now, if we deduct from 242.2 gm. of glucose eliminated, the 132 gm. of carbohydrate taken, we have 110.2 gm. to be derived from the proteid. Upon a theoretical basis of 60% of carbohydrate, this protein ought to provide 85.68 gm. of the same. It is easily seen that the elimination exceeds both the actual carbohydrate taken and that theoretically to be derived from the protein, so that utilization is absolutely lost and that the individual is living wholly on her own protein constituents since, evidently, after this long period, the depots of glycogen must be exhausted. Of course we may have two probabilities left; first, that fat may serve as a source of sugar, and, secondly, that the sugar to be derived from the protein may be much larger than ordinarily reckoned; in fact, some state that it may be as high as 90%. At least in this individual potato starch is no better utilized than wheat starch, and apparently all the levulose is eliminated as dextrose, for the sugar estimations were made with the polariscope and are likely to be larger, if anything, than those stated on account of the probable presence of oxybutyric acid where diacetic acid is so marked. The patient died June 10, two months after the last examination, of diabetic coma, having passed out of our care. Incidently, from April 8 to the fatal termination, the high-frequency current was used most faithfully by another physician, which explodes another much-vaunted cure.

From the rapidity and severity of the disease, as well as from the fatty diarrhea, this case was supposed to be of pancreatic origin, though no tumor of the pancreas was ever discovered and the possibility of the dependence of the diabetic condition on the general arteriosclerosis must always be borne in mind.

Another instance of the same marked deterioration of the carbohydrate utilization can also be seen in the following case:

April, 1905, J. G., druggist, aged forty years; has lost 30 lb. in the last five months. His weight when first seen was 147 lb., the appetite was fair and thirst was not marked. The fasting urine after eighteen hours abstinence from food contained 1.5% of glucose. On a partially restricted diet containing 60 gm. of bread and no sugar but vegetables *ad libitum* there were passed 1545 ccm. of urine with 33.32 gm. of glucose. Acetone was abundantly present but there was no diacetic acid.

September, 1905. Upon a strict antidiabetic diet to which 120 gm. of white bread (72 carbohydrate) and 100 gm. of potato chips (20 gm. carbohydrate) the total day's urine was 2720 ccm. with 60.1 gm. of glucose. Deducting the 60 gm. of glucose eliminated from the 92 gm. taken we have an utilization of + 34.7%. The patient was then placed on a protein-fat diet without carbohydrates and in November the urine was free from sugar.

January, 1906. By this time the weight had diminished to 129 lb. Upon an antidiabetic diet with 90 gm. of bread (54 carbohydrate) 100 gm. of Saratoga chips (20 gm. carbohydrate) and one liter of milk (40 carbohydrate) 3000 ccm. of urine were passed in a day with 142.5 gm. of glucose and abundant acetone. Deducting from the glucose eliminated the 114 gm. of carbohydrate in the food, 28.5 gm. were left coming from the proteid. Unfortunately the exact amount of protein taken was not determined, but in spite of the previous abstention, the tolerance for carbohydrate had grown steadily less and the utilization factor was minus. An examination of the feces at this time showed a large amount of fatty acid and soap crystals, numerous muscle fibers with striæ present and fragments of mucus intimately mixed with the feces.

June, 1906. With only 120 gm. of bread (72 carbohydrate) the day's urine contained 198 gm. of glucose with abundant acetone, but no diacetic acid, showing a gradually diminishing tolerance for carbohydrate in spite of a long period of treatment with the high-frequency current. The patient died in July of the same year.

From these instances of varied sugar metabolism we may learn, I think, that a + utilization indicates a hopeful outcome of the disease, and though the patient may have to maintain a moderate deprivation of carbohydrate food for a long period, and possibly for life, yet after a time a diet in which sugar alone is eliminated may be possible. In a restricted diet, however, too strong a warning cannot be given against the so-called gluten breads, which are always exploited as containing a large protein content, but nothing is ever stated in regard to the amount of starch contained, or at least the term "practically starch free" is used. If the amount of protein is worthy of being accurately stated in terms of per cent, certainly their starch is worthy of the same treatment and they could then be much more intelligently employed, for it would be easy to add the amount of carbohydrate ingested in this way to that taken in other ways, so that a basis for our calculation of utilization could be had. It has been my experience in the use of every diabetic bread but one, and that not particularly palatable, that even their restricted use causes an increased elimination of sugar when the utilization factor is 0, which can be determined, as stated above, either by the collection of the urine after twenty-four hours fasting or comparing elimination with the intake; three possibilities are always present: either that the tolerance will remain stationary, that it will increase, or that it may diminish. By complete removal of starch and sugar for a period, during which the urine should be carefully watched for sugar and particularly for diacetic acid, we can soon determine in which direction the indications with reference to tolerance point and govern ourselves accordingly. If the utlization is minus and the body cannot even oxidize the amount of sugar that theoretically ought to be derived from proteid containing not more than 10 gm. of nitrogen daily, then tolerance has reached its lowest ebb and there is very little likelihood that restoration will take place. Such individuals usually die from steadily increasing acidosis. In the determination of the utilization factor where actual weighing of food is not practical, as in private families, the diet charts of Dr. Arnold are of great assistance and, while not absolutely as accurate, of course, as weighing each article of food, serve admirably for an approximate estimation of tolerance.

## PROGNOSIS AND TREATMENT OF TUBERCULOSIS OF THE ANKLE IN ADULTS.

BY MARK H. ROGERS, M.D.,

*Assistant Orthopedic Surgeon to Out-Patients.*

(From the Orthopedic Department of the Massachusetts General Hospital.)

THIS paper is a study of the results in the treatment of tuberculosis of the ankle-joint in adults, and is based on the cases at the Massachusetts General Hospital during the last seven years. This study was undertaken because the treatment of this condition has not been satisfactory and because there has been a lack of knowledge as to what can be accomplished by the various procedures. The following points will be emphasized, namely, that the treatment of adults is different from that of children; that the duration of treatment must be shortened; and that in order to do this, more radical steps must be taken in the beginning of the disease.

There were twenty-three cases of tuberculosis of the ankle-joint during the last seven years on which this study is based, and of these, seventeen have either been traced by letter or the final results known by the records. A few cases have been omitted because of a doubt as to the correct diagnosis

Of the six cases which cannot be traced, three were seen but once at the clinic and, therefore, no conclusion can be drawn from them. Two cases were advised to have an amputation because of the extent of the progress, and probably this has been done at some other hospital. The other four were not observed long enough to establish any definite line of treatment. The remaining eighteen cases, of which there are fairly completed records, have been classified under the heads of fixation, operation and amputation. Practically all the cases were put on fixation treatment at first, and most of those that have had an amputation performed have also had an attempt at removal of the tuberculous focus. Under the heading of operation, I have included those cases that have had more or less thorough curettage of a tuberculous cavity or a resection of bone and joint. A tabulated list of these cases will be found at the end of this paper.

In a careful analysis of a large series of cases of tuberculosis of the ankle-joint from the Children's Hospital clinic made by Dr. Sever, which includes only children, it is evident that fixation and removal of weight-bearing has produced the best results and that the length of time of treatment was shorter than by the operative treatment. This is possible with a child by means of plaster-of-Paris bandage, or a brace, and high sole and crutches, and can be continued for a long period of time without very much effect on the mental condition of a child. But with adults it is an entirely different proposition. If we could say that at the end of six months or a year of such treatment there would be a functional cure without much danger of further trouble, then it would be justifiable to undertake it in every case, which means practically cessation of work.

In this series there were three cases, I, II, and III, treated throughout by fixation and partial removal of weight-bearing. Case I did not use his foot for four years, using a home-made artificial stump attached to the flexed knee-joint, and during this time he was able to do light work driving a team. He reports now that he is able to walk without crutches, although his foot is still weak. Case II was a boy of sixteen when he began treatment in 1904, and he was under close observation for four years. He now has a fairly serviceable foot which is in a position of equino-varus, but causing no symptoms. Case III developed tuberculosis of the ankle four years ago and she had fixation and crutches for one and one-half years. Then she had a quiescent foot without symptoms until a few months ago, when she began to have pain, due to the equinus position. This has since quieted down under fixation and she is still under treatment.

The results of treatment by fixation, the method which is preferable in children, and which is always used at first in adults, show that only three cases of these series obtained a useful foot and that the duration of treatment to accomplish this was at least four years. This is too long a period and the results are not sufficiently good to justify this procedure, except in selected cases.

Under the heading of operation, I have included those cases that were treated by incision and drainage, by curettage of a tuberculous sinus, and by complete resection of the tuberculous material. In this class there were six cases, three having a complete resection of the ankle-joint to remove as much of the focus as possible, and three having the simpler procedure of incision and drainage of an abscess with mild curetting.

These last three cases, VII, VIII and IX, illustrate very well the tuberculous process of a milder degree and the walling-off of such a process with the formation of a residual abscess. Case IX developed tuberculosis of the ankle-joint at five years of age and had no further trouble until he was thirty years of age, when an abscess developed. This was opened and within four months the sinus had closed. This represents a residual abscess, thoroughly walled-off and easily cured. Cases VII and VIII had a mild process for two years and were treated by partial fixation. Then after the foci was thoroughly walled off there developed abscesses which were curetted and drained, with sinuses remaining for a few months. They both report very satisfactory results with practically no symptoms. These three cases represent bone tuberculosis of not a very virulent type and are cured cases after treatment lasting two years.

The other three cases in this group of operative results, IV, V and VI, will be taken up in more detail in regard to the ultimate result, the length of time required to obtain a cure, and the amount of invalidism involved, because this method of treatment, complete eradication of the process, is theoretically the rational method.

In adult tuberculosis of the knee, the shoulder and the elbow-joint, in such cases as do not show a tendency to be self-limited and to become walled-off, a complete excision of the process, which means the whole joint, is recognized as the best procedure. A careful study of the x-ray findings in this series of cases shows that the most common situation of the focus is in the astragalus, with extension to the articular surface of the os calcis, tibia and fibula. If a resection is performed in the beginning, before the process has become widespread, an astragalectomy would remove the disease, but as a rule when this complete operation is undertaken it is necessary to remove much more. A good deal of bone tissue may be removed from the foot and still have finally a serviceable foot, if the tuberculous process will quiet down.

Those cases that have had an amputation performed have almost all had an attempt at a more or less complete operation first. There are only three cases that had this complete operation with a known end-result without amputation. Case VI was operated by the complete method in 1908, and now after two years of incapacity from work is using his foot constantly without symptoms in the occupation of a peddler. This is a very good result and compares favorably, with regard to length of time, with any other treatment. Case IV has a serviceable foot after two years of crutches. He can now walk without braces and complains only of some weakness. He has not worked because of tuberculosis of the lungs. Case V had a complete resection, and for some months afterwards there were many discharging sinuses. He developed acute tuberculosis of the lungs three months after the operation and has since died.

This makes only two cases out of eight that have a favorable end-result following a resection of the joint or an astragalectomy. The probable reason for this low percentage of cures by the method, which is theoretically correct, is that it is not undertaken until fixation has failed to arrest the process. In order to obtain good results, resection must be done when it is possible to remove the focus and not when several joint surfaces are involved.

| Case. | Age. | Date. | Duration of treatment. | Fixation. | Resection. | Amputation. | Remarks. |
|---|---|---|---|---|---|---|---|
| **FIXATION.** | | | | | | | |
| I. | 41 | 1905 | 4 years. | 4 years. | | | Was treated by Bier's hyperemia and fixation for two years. He reports that his foot is fairly strong, and is evidently a good result. No sinuses. |
| II. | 16 | 1904 | 4 years. | 2 years. | | | There are no sinuses now and foot is rigid and serviceable. Good result. Now has tuberculosis of lung. |
| III. | 20 | 1910 | 2 years. | 2 years. | | | Slight recurrence of symptoms after four years on account of foot strain. Good result. No sinuses. |
| **RESECTION.** | | | | | | | |
| IV. | 37 | 1909 | 1½ years. | 5 months. | Astragalectomy. | | Under fixation, condition became worse. After complete resection, discharging sinuses for six months. Now he can walk without crutches. Good result. Tuberculosis of lung. |
| V. | 36 | 1909 | 1 year. | 3 months. | Astragalectomy. | | Condition grew progressively worse with discharging sinuses. Developed tuberculosis of lung. Dead four months after operation. |
| VI. | 25 | 1908 | 2 years. | 6 months. | Complete. | | Two years without working. Now is able to walk without symptoms. Very good result. |
| VII. | 33 | 1908 | 3 years. | | Incision and drainage, 1908. | | Slowly developing process caused by drainage of abscess. Residual. Good result. |
| VIII. | 19 | 1908 | 4 years. | | Curettage, 1909. | | She used crutches for three years. Discharging sinus in 1907 and 1909. Residual abscess curetted 1909. Good result. |
| IX. | 30 | 1910 | | | Curettage, 1909. | | Tuberculosis ankle in childhood. Residual abscess which drained for four months. Good result. |
| **AMPUTATION.** | | | | | | | |
| X. | 45 | 1905 | 2 years. | 3 months. | Complete, 1905. | 1907 | After resection, sinuses and sepsis for one year. |
| XI. | 30 | 1905 | | | | | Amputation about two years later. Very good result from amputation. |
| XII. | 14 | 1900 | 9 years. | 8 years. | Curettage, 1904. Curettage, 1907. Resection, 1908. | 1909 | Was operated three times. Reports that she is very glad to have artificial leg. |
| XIII. | 18 | 1909 | 1 year. | | | 1910 | Reports that artificial leg is very satisfactory. |
| XIV. | 35 | 1908 | 3 years. | | Astragalectomy, 1908. | 1909 | Discharging sinuses after resection. She is very grateful for having an amputation. |
| XV. | 46 | 1905 | 2 years. | | Astragalectomy, 1905. | 1906 | Continuous sinuses and sepsis after resection. |
| XVI. | 28 | 1910 | 9 months. | 1 month. | Exploratory operation. | 1910 | Advised amputation after exploratory. Process too widespread to remove. |
| XVII. | 17 | 1903 | 5 years. | 1 year. | Astragalectomy, 1904. | 1908 | Discharging sinuses for three years after operation. |
| **DISAPPEARED.** | | | | | | | |
| XVIII. | 42 | 1907 | | | Exploratory incision. | | Advised amputation. Process too far advanced. Disappeared. |
| XIX. | 18 | 1908 | | | | | Recommended for amputation. Disappeared. |
| XX. | 27 | 1904 | | | Incision. | | Disappeared. |
| XXI. | 20 | | | | Incision. | | Disappeared. |
| XXII. | 27 | 1910 | | | | | Disappeared. |
| XXIII. | 24 | 1910 | | | Incision. | | Is being treated elsewhere. |

Eight of the seventeen cases, 44%, have had an amputation performed at the point of election. Most of them have been treated by other methods before an amputation was advised, first by fixation, generally until there was evidence of abscess formation, then by an attempt to remove the focus, with result that there were sinuses which showed no tendency to heal.

It is of interest to note that the cases which seemed to do poorly, following an erasion of the focus, were acute and early in the course of the disease showed no tendency to become walled-off. Such cases show a virulent form of tuberculosis and there is an early spread of the disease from the articular surface of the astragalus to the various joint cavities of the ankle. Compare the duration of symptoms of these cases before beginning treatment with the cases VII and VIII, which were cured by simple incision and drainage of abscesses.

The general feeling of the patients that have had an amputation, judging from letters received, is one of satisfaction in being able to work and to be free from dressings. The desire of the patient and of the surgeon is very strong to save a foot from amputation, but I have been impressed by the tone of the letters showing gratification after an amputation is done.

The length of time necessary to effect a cure in these eighteen cases, by any method of treatment, has been from two to four years anyway, and some have extended over eight years. This question should be fully considered in giving a prognosis in any given case and in planning out a course of treatment. It is too often the case that a man has been carried along for three or four years, being compelled to give up his work with the hope of an ultimate cure, and at the end of that time it may be found that he is in such a mental state that he is not capable of work. A man employed as a mechanic can quit work for four to six months and then take up his trade, but as a rule he cannot quit for four years and then be capable of earning as before.

As an example, Case XVI of this series was first seen after he had had trouble with his foot for seven months. At this time his ankle was swollen and indurated, the motions were limited somewhat by muscular spasm. The x-ray showed some destruction of bone, involving the upper surface of os calcis and the astragalus and a small focus in the articular surface of the fibula. Up to this time he had been able to continue work. From a study of the x-ray it seemed possible to remove the foci and save the foot. An exploratory incision was made with the idea of doing a radical excision of the diseased bones, if it were thought best. But when the joint was opened it was found that the process had extended both in front and back of the astragalus, and to remove the tuberculous material would require a very radical procedure, without any surety of an immediate cure, and a strong probability that it would take many months of drainage and three or four years of semi-invalidism. He was advised to have an amputation, which was accepted a month later so that he could go back to work in a comparatively short time, and could soon adjust himself to his changed condition. And yet from the patient's standpoint it was a great temptation to try and effect a cure by a resection. He is much better off with an early amputation than he would be at the end of three years with a foot that is healed and quiescent but not strong.

The attempt at a resection should be made in the very beginning of the process, before there is much involvement of the joint, or even before necrosis has extended beyond the bone itself. In order to do this, the diagnosis must be made early when the x-ray shows a very small focus. This is the time when the choice between fixation and a more radical procedure must be made. But according to this series, only two cases out of eighteen were cured by the fixation method and simple curetting of a residual abscess in less than four years, which is too long a time for the good of the patient. It takes courage to advise a radical resection in the very beginning, and it takes courage to advise an amputation in a case where there is a slight possibility to effect a cure by resection, but it is evident that both should be done in order to shorten the duration of invalidism and to cure the patient rather than the disease.

From a study of these cases it is clear that fixation is not sufficient to control tuberculosis of the ankle-joint in adults in a large percentage of cases, and even in mild cases it requires a long period of time. Chronic invalidism, meaning by that a certain mental condition that these people are sure to reach, when they are of no use to society, should be avoided. This can be done by an early diagnosis, and by outlining the treatment so that the end-result is obtained within one or two years.

A complete operation, a radical removal of the focus, should be performed before there is much involvement of the various joint-surfaces, and it should not be undertaken only because fixation has failed. Better results can, undoubtedly, be obtained if this is done as soon as the diagnosis is established, and seems justifiable since fixation is not sufficient.

Amputation has been necessary in over 50% of these cases. It should be advised when the process has invaded several joint-surfaces especially posterior to the astragalus. The results of amputation are good from the patient's point of view, and an artificial leg is much preferable to long-continued dressings and sinuses. The length of time of treatment should be diminished to within two years.

## SOME PROBLEMS OF SCHOOL INSPECTION.*

BY WM. PEARCE COUES, M.D., BOSTON.

THE necessity and importance of the work of medical inspection of school children needs no brief before such a conference as this. It will be of interest to consider a few general topics and

* Read at the Boston 1915 Health Conference, Feb. 20, 1911.

then to take up some points in regard to the work in my own district.

It is a cause for congratulation that the work of school inspection has grown in other cities in this country and abroad. Only a short time ago the literature on this subject was extremely meager. Now it is voluminous, and every general medical journal has articles upon the subject at frequent intervals.

The conception of the school inspector's duties has changed correspondingly with the increase in the knowledge of the importance of the health of school children as a future necessity to the welfare of the community or nation.

The former idea that the school physician was one whose duty was solely the examination and exclusion from schools of pupils afflicted with contagious diseases has changed with the awakened interest in the hygiene and safeguarding of the health of the child.

The necessity for more exacting and general examination of children with this end in view has brought about the present agitation concerning school inspection and the numerous contemplated changes which have been proposed in this city.

Naturally the work of school inspection differs much in different districts in a city. The immediate proximity of certain schools to the large and recent foreign population causes a preponderance of certain diseases in these districts. Thus we find parasitic skin diseases and general contagious diseases common in these localities. The further from these centers the outlying districts are, the fewer, as a rule, of these troubles will be found.

The necessity for school inspection in a community is in inverse ratio to the knowledge and intelligence of that community. We have found in the work in our district that rarely is it through willful negligence that parents or pupils do not follow out the suggestions given, but rather through a failure to grasp their importance through ignorance.

One of the most important steps in the development of school inspection in Boston was the establishment of nurses[1] in the schools. This advance, at first tentatively tried, through the Boston Instructive District Nursing Association, proved such a success as to be permanently adopted by the School Board. It would be hard to state too emphatically how much good this has accomplished. Before the school nurse's advent, the school physician was handicapped to a great degree in his efforts. His suggestions as to treatment by the family physician or the hospital might or might not be carried out,— there was no way of being sure. The nurse filled this gap and saw that the children received the treatment that the physician suggested.

The medical inspection law of 1906 has done much to put medical inspection of schools on a sound basis in this state, and naturally has also added to the labors of the school physician. To make the work still of wider scope is the idea and aim of those who have the best interests of school inspection at heart.

At present the school inspector in his routine work sees only the cases referred to him by the teacher or those that the nurse happens to find. It is obvious that such a plan makes incomplete work and puts the question of decision on the teacher oftentimes. The necessity of some change which would enable the nurse to see all the pupils and refer them to the physician as necessary is apparent.

One of the numerous criticisms of the work is that, as there is no law obliging parents to take their children for treatment of the troubles found by the school physician, his work is useless except for the old primary object of school inspection,— the detection and isolation of contagious disease.

Judged from the experience we have had in this district, nothing could be more untrue. Of all the parents and guardians interviewed by the school nurse for the school physician last year, it is doubtful if 1% were unwilling to have treatment prescribed for their children. In answer to the criticism that no good is accomplished by the present system, I would give the following general figures. It is realized that they represent the work of only one district, but I know that there are many school physicians doing the same work. During the last school year, the school nurse escorted 860 children to hospitals for the treatment of various ailments, all of which were treated. It is estimated that the parents took an equal number directly to hospitals on the school physician's advice; still others were referred to their family physicians and treated by them.

The inadequate and unhygienic school accommodations for many of the school children add to the ailments of the children for which the school physician's advice is required. It would be a wise and health-giving measure should the School Board cut off every unessential of the school course and put this money into adequate accommodations for the children.

To make the work of school inspection more effective under the present régime, a suitable room should be provided in all the schools for the examination of pupils. There should be the simple, necessary things to facilitate proper examination. At present there is no proper place to examine a child in the recumbent position in any school in my district. How are the school inspectors to to their work to the best advantage without such necessary aids? It is well known that the examination of a heart case is practically worthless unless the child is examined recumbent as well as standing. Moreover, it is essential to have a place of examination in each school building so that the work of school physician and nurse can be carried out with as little disturbance to the school routine as possible.

In the past year we have made numbers of examinations of large groups of children for vari-

[1] Coues, W. P.: The Medical Inspection of Schools in Boston, the Present Limitations and Future Possibilities. Boston Med. and Surg. Jour., vol. clx, 1909, p. 746.

ous purposes, such as fitness for the open-air classes, mental retardation and throat and teeth examination. Without burdening you with many figures, some few may be of interest concerning the retarded pupils. These children had all been in the same grade more than a year, and it was thought best to see if there were any marked and readily found physical causes which might be a factor in the mental backwardness. One hundred and fifty-eight pupils were examined.

Forty-one, or $25\frac{9}{10}\%$, had defective vision; 2, or $1\frac{2}{10}\%$, had defective hearing; 122, or $77\frac{2}{10}\%$, had chronically enlarged tonsils; 127, or $80\frac{3}{10}\%$, had defective or carious teeth; 34, or $21\frac{5}{10}\%$, had marked pallor (the Hb not estimated); 3, or $1\frac{8}{10}\%$, were markedly undersized; 1, or $\frac{6}{10}\%$, was extremely nervous without definite signs of chorea.

Practically all of these children have been sent to the proper sources for treatment of these various conditions. It is of interest to compare the result of the examination of the teeth and throat of these children with that of 212 children of normal mental caliber looked over last year.[2] Seventy-two per cent of these children showed chronic enlarged tonsils; 50% showed carious teeth. Comparing, we have 212 average children; 72% had chronic tonsils; 158 retarded mental development; $77\frac{8}{10}$ % had chronic tonsils. Two hundred and twelve average children, 50% had carious teeth; 158 backward children, $80\frac{3}{10}\%$ had defective or carious teeth. It would seem from these statistics that chronically enlarged tonsils and the generally accompanying adenoids had little to do with the mental backwardness of these children, but that carious teeth might play a considerable rôle in the causation of this condition.

In conclusion, no one is more alive to the inadequacies of the present system of school inspection than the school physicians themselves. At the same time, a large amount of work of direct benefit to the children has been done by school inspection.

Dr. Durgin and those directly associated with him in the Board of Health are the only ones who have an intimate knowledge of the truth of this statement. The general public is absolutely ignorant of the true state of the case and the public press seemingly willfully ignorant of it.

When the public is better educated as to the necessity and importance of school inspection, better results may confidently be expected.

---

THE State Health Department has had made a list of the lepers now in the state of Texas, who number 30. Of these, 11 are reported married and 9 single; 10 are severe cases, 2 medium and 6 mild; 20 are said to be Americans and 2 Mexicans; 16 are male and 6 female. As to location, 11 are in Galveston, 8 in San Antonio, 3 in Dallas, 3 in Sourlake and 1 each in Liberty, High Island, Del Rio, Comfort and Austin. They vary in age from thirteen to sixty-eight years. — *Jour. Am. Med. Asso.*

## TUBERCULOUS MENINGITIS, WITH LEUCOCYTOSIS AND A PURULENT EXUDATION CONTAINING MANY BACILLI. A CASE REPORT.

BY I. CHANDLER WALKER, M.D.,
*Medical Interne, Carney Hospital, Boston, Mass.*
(From the Medical Clinic of the Carney Hospital, Dr. Henry A. Christian, Physician-in-Chief.)

IF the spinal fluid obtained by lumbar puncture is turbid and if this turbidity is found to be due to polymorphonuclear leucocytes, one is naturally inclined to the diagnosis of acute meningitis caused by some one of the pyogenic cocci. In some cases it is very difficult to find typical cocci in meningeal fluids, so that the absence of cocci in the smears might not lead one to suspect some other bacteria not easily stained by the ordinary methylene blue stains. In this way it is quite possible to overlook a case of tuberculous meningitis presenting a turbid polymorphonuclear leucocytic exudate, especially since most of the textbook and system discussions of tuberculous meningitis emphasize strongly the non-purulent character of the spinal fluid and the prominence of lymphocytes in the fluid. That cases, however, do occur showing the above described type of spinal fluid caused by the tubercle bacillus is emphasized by the following case.

P. B., age nineteen, admitted to the Carney Hospital Oct. 6, 1910.

*History* (obtained from patient's mother). —The patient had been perfectly well, mentally normal and had worked as a plumber's apprentice up to the middle of July, 1910. At this time he became ill with [1] "typhoid pneumonia." He was confined to his bed for five weeks. During this illness the patient had no abnormal mental symptoms. He appeared to have perfectly recovered from the illness and worked the following three weeks. On Sept. 3, 1910, he became ill with "pneumonia." [1] In the beginning he had pain in his left chest, and a few days later he complained of severe headaches unaccompanied by vomiting. On Oct. 3, the patient failed to recognize his mother and became violently delirious. During the next three days there was no change in his condition, and he was brought to the Carney Hospital. On admission, Oct. 6, 1910, his temperature was 101.5, his pulse 110, his respirations 36 to the minute.

Physical examination showed an emaciated but fairly well-developed young man lying in bed with his head slightly retracted and turned towards the right side, his legs acutely flexed on his thighs and trunk, and breathing rapidly though not laboredly through a widely opened mouth. There are some fibrillary twitchings of the muscles of the arms and legs and the arms are constantly being moved about in a semi-purposeful manner. The patient seems to vaguely notice his surroundings, but he makes no response when addressed.

*Eyes.* — Both eyes are kept constantly rolled up under the lids with a slight tendency to direct the pupils upward and to the left. There is no evident strabismus. The pupils are moderately dilated, both are irregular, the left possibly is slightly larger than the right. No definite reaction to light is obtained, although both pupils are constantly altering their size.

*Ears* reveal no discharge, and there is no mastoid tenderness.

[1] Diagnosis as stated by the patient's mother.

*Lips, teeth and tongue* are covered with dry sordes. Tongue lies in the middle of the mouth, is protruded in the mid-line.

*Throat* is negative.

*Neck* is held rigidly and slightly retracted. Attempts to bring the head forward appear to elicit pain.

*Glands*, cervical, axillary, right epitrochlear and inguinal, are palpable, not greatly enlarged.

*Thorax* is long, narrow and symmetrical. Expansion is good and equal on the two sides.

*Lungs*. — Everywhere in front there is resonance, and no râles are heard. In the left back below the level of the spine of the scapula there is dullness, and a few scattered fine moist râles are heard. In the right back below the angle of the scapula the percussion note is flat, there is a decreased transmission of breath sounds and many fine and consonating râles are heard.

*Heart*. — The apex beat is palpable in the fifth interspace 3¾ inches from the mid-sternal line. On percussion the left border of the heart corresponds with this position of the apex beat, while the right border is one inch to the right of the mid-sternal line, and the upper border is at the lower margin of the third rib. The heart action is regular, the sounds are of a weak and poor quality, unaccompanied by murmurs.

*Abdomen* is moderately distended, tympanitic throughout except in the right flank. There is no shifting dullness, no palpable masses.

*Liver* dullness extends from the sixth rib to the costal margin, edge not palpable.

*Spleen* not enlarged to percussion, edge not palpable.

*Genitalia* are small, no palpable masses or areas of tenderness.

*Extremities*. — Marked atrophy of the calves and the thighs. Muscles of the arms and legs are spastic, but the spasticity is easily overcome. Positive Kernig sign is elicited on both sides.

*Reflexes*. — Arm reflexes cannot be elicited. Right knee-jerk is present, the left absent. Both Achilles reflexes are present, but the left one is sluggish. There is a positive Babinski sign on the left side; on the right the plantar reflex is normal. There is no ankle clonus, no cremasteric and no abdominal reflex present.

*Skin* shows no rash. There is some redness over the bony prominences, but no decubitus.

*Blood*. — Hemoglobin 85%, white blood cells 22,400. Smear shows a polymorphonuclear leucocytosis, no other abnormality. Widal reaction negative.

Oct. 7. Patient is quite irrational, but will protrude the tongue and close the eyes when requested. The legs are held flexed and are immediately returned to this position after forcible extension. The patient is incontinent. His temperature is 99.6, pulse 120, respiration 60 during the forenoon. Under chloroform anesthesia a lumbar puncture was performed and 40 ccm. of turbid fluid was removed under a moderate increase of pressure. Thirty cubic centimeters of Flexner's anti-meningococci serum was injected. The patient's condition remained unchanged during the day, and the evening temperature was 101.2, pulse 140, respiration 60.

Oct. 8. The patient is gradually failing. He is in a state of stupor. Respirations are Cheyne-Stokes in type, temperature 102, pulse 134, respirations 60, with periods of apnea lasting for twenty seconds.

Oct. 9. The patient is distinctly worse, temperature is 104, pulse 150, respiration 70, still of Cheyne-Stokes type. The patient became increasingly stuporous and died four hours later.

*Examination of the spinal fluid*. — Amount, 40 ccm.; turbid, not blood stained. Specimen was centrifugalized in a sterilized tube. Smears from this sediment showed a great predominance of polymorphonuclear leucocytes, there being 98% of polymorphonuclear and 2% of mononuclear cells. There were also present very many bacilli, acid-fast, and not decolorized by the Gram's method. These bacilli resisted decolorization by 10% nitric acid after carbol-fuchsin staining for fifteen minutes.

Two guinea pigs were injected, each with ½ ccm. of the spinal fluid, one subcutaneously, the other intraperitoneally. The guinea pig injected subcutaneously died three days after the injection with a subcutaneous abscess at the site of injection. Smears made from this abscess showed an acid-fast bacillus. Material from this abscess was rubbed up with sterile water and injected subcutaneously into a guinea pig. This guinea pig killed three weeks later showed the same acid-fast bacillus present in caseous areas in the spleen. The guinea pig which was injected intraperitoneally with spinal fluid was killed three weeks later, and at autopsy the peritoneum was found to be studded with small tubercles, and in the liver, spleen and omentum there were small foci of caseous material. Sections from these areas showed under the microscope miliary tubercles with giant cells and caseation. In these sections an acid-fast bacillus was found.

### SUMMARY.

A young adult with physical signs of meningitis, fever and leucocytosis shows on lumbar puncture spinal fluid turbid, containing 98% of polymorphonuclear leucocytes and very many bacilli, with the morphological and tinctorial peculiarities of the tubercle bacilli, yielding by animal inoculation the typical lesions of tuberculosis. The case is reported to emphasize the fallacy of diagnosing meningitis as due to pyogenic cocci from obtaining a turbid spinal fluid containing a large excess of polymorphonuclear leucocytes.

## THE PUBLIC HEALTH LABORATORY.*

BY S. L. ARMS, M.D.,

*Director of the Bacteriological Laboratory of the Boston Board of Health.*

THE first public health laboratory was established in 1888 by Dr. Gardner T. Swarts, of Providence, R. I., but since that time laboratories have become such a necessity that they are found in nearly all large cities, and the states with but few exceptions also have laboratories in order that they may do the needed work for the smaller towns and cities which would otherwise be unable to have that service and also to do the larger or state problems,— as water and sewage work, food and drug analysis and medico-legal examinations. Besides the large cities and states, a constantly increasing number of smaller cities and towns have municipal laboratories and keep constant supervision over contagious diseases and the milk supply.

At the outset, the aid of the laboratory was most frequently asked in the diagnosis of diphtheria, but at the present time there are many other ways in which they may aid the physician.

In order to render the best service there should

* Read at a meeting of the New England Pediatric Society, Feb. 25, 1911.

be co-operation between the medical profession and the laboratory, each doing what it can to aid the other, and both working together for a common purpose — the betterment of the public health.

A few ways in which the laboratory can aid the physician are:

First. Correct diagnoses.

Second. Earliest possible report.

Third. Reports to the physician of just what is found.

To take these up a little more in detail, of course it goes without saying that unless the diagnoses are reliable, the physician very quickly loses confidence in laboratory reports.

Let us consider for a moment a few possible sources of failure to get a positive culture from a case of diphtheria:

First. The bacilli may be localized and the swabs fail to become infected.

Second. There may be organisms present which overgrow the Klebs-Loeffler even when incubated for fifteen hours, the optimum time for diphtheria.

Third. In laryngeal diphtheria, especially in an infant, it is extremely difficult to obtain a swab from the seat of trouble.

As to the report, in order to do the greatest amount of good, the diagnosis must be known to the physician as soon as possible, and in municipal laboratories this can be done by telephone, many laboratories reporting in this way all positive diagnosis cultures and positive smears from the eyes. Of course it is impossible to report all examinations by telephone, this being followed by a mail report in all cases, and these in turn being sent as early as possible.

There are many times when a simple positive or negative report should not be given, and in these cases a few words may help the physician considerably.

The physician can aid the laboratory in many ways: Each outfit contains a card with blanks for data, and if these are filled out in full it makes them of much greater value for statistical purposes.

By reporting to the laboratory any failure in the service, such as inability to obtain outfits at any station or failure of any station to send outfits in promptly, and also by letting the laboratory know it if can be of service to him in any way.

There is probably no way in which the public health laboratories can aid the pediatrician more than in its work toward improving the milk supply, and they are ready to do much more. Boston is particularly fortunate in having the services of Prof. Jas. O. Jordan at the head of this department. I wish to quote from an address delivered by him at the quarterly meeting of the Massachusetts Association of Boards of Health, October, 1907: "Those who desire clean milk must be willing to pay for it. But clean milk, regardless of price, is the cheapest variety to purchase.

"Outside the price question, the public unfortunately is not earnestly interested in the milk problem. The quality even is not considered with enough seriousness to cause many consumers to go to a slight personal inconvenience to ascertain the facts concerning their supplies.

"The experience of the Bureau of Milk Inspection of the City of Boston supports this contention, for although the consumers of that city have been for years invited to avail themselves of the opportunity of having their supplies examined free of charge, not in recent years have enough purchasers taken advantage of this offer to average one sample a day."

During 1910, 399 samples were brought in by consumers.

There is still a great deal of work to be done from the educational standpoint not only of the public, but the profession as well, when a statement like the following can be taken from the annual report of the health department of a city with a population of over three hundred thousand, and the bacteriologist making this report was a physician.

"During the last two years the department has been making bacteriological counts of market milk.

"In 1908 there were 213 counts which showed an average count of 12,048,000 bacteria per cubic centimeter; 42% contained less than 500,000 bacteria per cubic centimeter; 14% between 500,000 and 1,000,000 bacteria per cubic centimeter; 21% between 1,000,000 and 5,000,000 bacteria per cubic centimeter, and 23% contained over 5,000,000 bacteria per cubic centimeter. This is not a very bad condition, as 56% contained less than 1,000,000 bacteria per cubic centimeter, and 77% contained less than 5,000,000 bacteria per cubic centimeter.

"In 1909 there were 194 counts which showed an average of 4,466,000 bacteria per cubic centimeter. Forty-two per cent contained less than 500,000 per cubic centimeter; 6% between 500,000 and 1,000,000 bacteria per cubic centimeter; 26% between 1,000,000 and 5,000,000 bacteria per cubic centimeter, and 28% more than 5,000,000 bacteria per cubic centimeter. While the average count of the year is much less than last year, the per cent of low counts is not quite as high. Forty-six per cent contained less than 1,000,000 bacteria per cubic centimeter, and 72% less than 5,000,000 bacteria per cubic centimeter.

"This work was instituted to find out about what the average bacterial count of our market milk would be, and to give us some definite statistics should we wish at any future time to establish a bacteriological standard.

"The result shows that at least 75% of the milk sold in this city throughout the entire twelve months of the year has a fair bacteriological content. Only about 25% of the milk examined contained an excessive bacteriological count. With the continued improvement shown, it is only a question of a short time when a bacteriological standard of 500,000 or 1,000,000 bacteria per cubic centimeter will not work

FIG. 1.

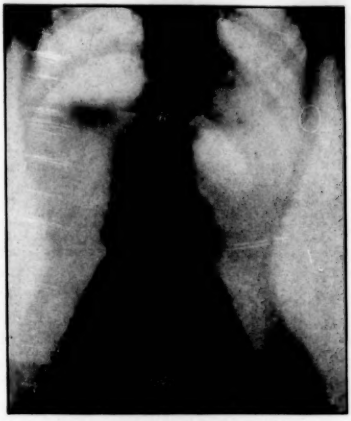

FIG. 3.

FIG. 2. X-ray of stomach in standing position. Note the downward position of the stomach and that it is considerably below the crest of the ilium.

FIGS. 3 and 4. Showing sagged stomach and colon. A coin marks the position of the umbilicus.

a hardship upon the dairymen and will be possible as a routine measure."

It will be remembered that the statement was made that only about 25% of the milk sold during the entire twelve months contained an excessive number of bacteria, but on examination of the table showing total number of laboratory examinations by months during 1909 we find that in May 6 counts were made, 15 in June, none in July and 12 in August; only 33 out of a total of 194 being made during these four warm months.

I am sure that every one present here to-night would consider, from the figures given, that considerably more than 25% of that milk contained an excessive number of bacteria and would also raise the question, How can he report with so much satisfaction on the gain in the entire twelve months when he made no tests in July? But 42% of the milk tested could have sought a market here.

I am glad to say that such a report as this is most unusual and I know of no other place where those having charge of the situation would be satisfied with a milk supply which averages 4,466,000 bacteria per cubic centimeter, or willing to have the great majority of the samples taken during those months when the counts would naturally be the lowest.

The majority of the health departments report a much better condition regarding their milk supply, and this is bound to improve.

Every dairy producing certified milk is an educational center, and their number and influence are continually growing.

Many farms are to-day producing clean milk and setting a good example to their neighbors.

In conclusion, let me add that the laboratory is ready to aid the physician in every possible way, but it can be readily seen that its field of usefulness is determined by the physicians themselves, or, in other words, the laboratory cannot aid the physician who does not use it.

## PREGNANCY AS A POSSIBLE RELIEF FOR VISCERAL PTOSIS.*

BY LLOYD T. BROWN, M.D., BOSTON.

THE medical journals lately have been paying more attention than usual to the subject of the ptoses and their connection with certain types of disease. It is not the intention of this paper to discuss the various causes of the ptoses, but I would like to give, if possible, a few ideas that have come to me since I have been paying attention to the human body more as a mechanical proposition than as a repository of an appendix, a gall bladder or a pregnant uterus. Formerly what happened to the curves of the spinal column when a patient was laid in an etherized condition on a hard, flat, operating table, or what effect this might have on the convalescence, never occurred to me or seemed to be looked upon as important by those I was working with. What happened to the viscera and the spinal curves during pregnancy and the puerperium, and the fact that these times might be used as a definite beginning for changing faulty postures and ptoses, also never occurred to me, but that such is the case I am going to try to show.

* Read before the Obstetrical Society of Boston, Jan. 24, 1911.

The type of woman who drifts from specialist to specialist with what is diagnosed as a neurasthenic or a functional back, and who may have all the distressing symptoms of neurasthenia, such as nervous indigestion, constipation and more or less pelvic trouble, is that type which is known as the round-shouldered, hollowed-back class. And this class is all that there is time to take up to-night.

Examination of such a woman shows the following differences from the normal or ideal type. I take this description in part from an article by Dr. Reynolds in the *Journal of the American Medical Association*, Dec. 3, 1910.

In a person who stands in the round-shouldered hollow-backed position, "the center of gravity is carried too far forward for easy maintenance of balance, and the capacity of the upper part of the abdomen is decreased by the forward droop of the upper dorsal spine and the descent and flaring of the ribs, while the relaxation of the anterior abdominal wall produced by the approximation of the ensiform cartilage to the pubes permits the formation of a pot-belly with consequent increase in the capacity of the lower abdomen." (See Fig. 1.)

Now, it is known and can be shown by x-ray pictures taken in the standing position after the giving of a bismuth meal that in this type of woman this pot-belly is occupied by the sagged stomach and colon, and that it is not, as is commonly supposed, fat. (See Fig. 2.)

Consider now the change that this position causes in the shape of the abdominal cavity, and what bearing this change may have on the pelvic organs. In a normally poised figure the axes of the abdominal and pelvic cavities are at nearly right angles, and the thrust of the former is such that it comes on the pubes and the strong fasciæ of the lower abdominal wall, with very little pressure into the pelvic cavity.

In a figure of the round-shouldered, hollow-back type, with the forward position of the abdomen or the pot-belly, the pelvis must be tilted forward, and this brings the thrust of the abdominal cavity against the loose anterior abdominal wall, which, on account of its attachment to the pubes, must push the contents of the pot-belly backward into the pelvis against the pelvic organs. From a large series of visceral x-rays that have been taken in this type of case, it is possible to conclude that practically all of these cases have a visceral ptosis either of the stomach and colon or of the colon alone. Therefore, it is the sagged abdominal viscera which occupy the pot-belly and which are consequently forced backward into the pelvis. (See Figs. 3 and 4.)

Considering that in this type of case constipation is the most common trouble, it is easy to

see that the weight of the sagged and clogged great bowel must come upon the pelvic organs and that this may be a possible cause for some of their malposition or displacements and the symptoms from them.

There is not time to consider what effects the sagged viscera may have, not alone on the digestion, but also on the general condition of the patient, and on the amount of reserve energy that she is able to store up for future use. But when one realizes that in the process of sagging not only the walls of the viscera themselves must be tremendously stretched and thinned out, but also that the splanchnic nerves and the blood vessels must undergo a similar stretching, the wonder is that there has been so little trouble, and it is more easy to understand why the taking of food in certain cases may be followed by distress which limits the amount able to be taken, as well as desired; and also why the consequent slowing up of the progress of the food through the intestinal tract may give more opportunity for fermentation and putrefaction and the absorption of these products with the resultant coated tongue, bad breath and lack of appetite for the morning meal.

Pregnancy in this type of woman often causes in the early months considerable mental as well as physical distress. For at this time all the pelvic organs are congested and consequently more sensitive to irritation or pressure from above. For the first three months, while the uterus is still a pelvic organ, it is a very common occurrence for the patient to have the so-called morning sickness, which usually lasts each day until the patient has been up and about for a period of time. May not this sickness be explained in this way? During the night, while the patient has been in the recumbent position, the hollow viscera have fallen back into their more normal place in the abdomen. When the patient takes up the standing position in the morning, the colon and its contents sag downward and press on the congested ovaries and uterus, with the resultant vomiting which lasts until the circulation readjusts itself or the viscera are allowed by the lax abdominal walls to sag forward and away from the pelvis. As a suggestion, it would be interesting to see if it would make any difference in the morning sickness if a patient were to roll on her face while still recumbent and then to get out of bed while still in this new position, or even better after she has put on a corset or belt which fits close enough around the lower abdomen to keep the viscera from sagging downwards.

When the uterus becomes an abdominal organ and keeps on enlarging and growing upward, then is the time that there should be some effect on the patient's general condition if there is anything in the theory that visceral ptosis is one of the chief reasons why certain women never seem to have any reserve force.

The uterus as it enlarges from below upwards gives the viscera the most perfect form of support imaginable, because it is always present and until the last month is constantly enlarging and, what is most important, it is present for five months. This last is particularly important, because it is a well-recognized fact that any muscle or ligament that is kept constantly on the stretch loses its power of complete contractility, and also that if such a muscle or ligament can be relieved of that strain for a period of time, it will tend by the natural laws of repair to return to its original normal condition. Now, as before mentioned, in pregnancy such a support is given to the viscera and applied in the best possible way. Consequently, there ought to be a change for the better in the condition of the patient, because the stomach and colon, being held up in position, must be able to digest and assimilate the food with much more freedom. That this is very often so seems to be the case, from the fact that most women usually gain weight which cannot be accounted for by the baby alone.

What happens to the bony skeleton during delivery, and how its relaxation may be taken advantage of, is so well known to you all that I pass this by and will turn to what is the most important part of all, the puerperium, because it is then that the treatment should be planned with the idea of doing everything possible which will help keep the woman in as good condition in the future as she was during the last months of her pregnancy.

The two chief points on which to lay stress at this time are the relaxation of the pelvic joints and the fact that the hollow viscera have had their support of the past few months entirely removed.

First, as to the pelvic joints. As the patient lies on her back, on a more or less hard bed, there is a constant pressure on the sacrum and the dorsal spine, and this must tend to flatten out the normal lumbar curve. This flattening puts on the stretch the spinal muscles and ligaments which are attached to the sacrum and the ilia and so prevents them from being able to contract properly and so protect the pelvic joints which in their relaxed condition especially need this protection. This lack of protection, when one considers the anatomy and the structures surrounding the pelvic joints, may be not only a possible factor in lengthening the puerperium, but also may be an immediate cause of the backache and after-pains which are not definitely due to the expulsion of blood clots and lochia. For methods to relieve this, anything should be done which will tend to take away possible strains and which will permit or assist the natural contraction of the muscles and ligaments. For this, great benefit can be obtained from the use of a small hard pillow, or folded towel, placed in the hollow of the back in order to support the lumbar spine. Or, in certain cases, the cross strapping of the low back with adhesive plaster will give the greatest possible support to the pelvic joints.

Concerning the removal of the support given by the uterus to the hollow viscera, we come to a more difficult and equally important problem. It is known that in the recumbent position the

viscera tend to take their normal position, and, therefore, anything which will help this tendency should be done. Therefore, it seems to me that the swathe, concerning which there used to be so much discussion, is a very valuable asset. But it should be properly applied. It should come down as low as, or lower than, the pubes in front, and should be fitted tightly around the pelvis, particular care being taken not to get the pressure so it is applied on the crests of the ilia, because this tends to separate the pelvic joints. A pad or folded towel should be placed so that it comes between the pubes and the umbilicus. Above the umbilicus and the iliac crests the swathe should be loose, as this is the region which is occupied by the stomach and transverse colon, and there should be plenty of room there.

In order to thoroughly carry out this idea of proper support, it is most important that when the time comes for the patient to be up and about, she should be given a properly fitting corset, with or without pelvic belt attached to it, this latter depending mostly on the amount of backache she had before pregnancy. The principal points to be careful about in selecting such a corset are to be sure and have no constriction about the lower ribs and upper abdomen; also that the corset should not press on the iliac crests, but should fit snugly about the pelvis.

Exercises are very important and should be begun as soon as the danger of an embolus is passed. These should consist at first in general massage, and later in active motions of the legs and arms. All straight leg raising, which, of course, puts all the strain on the pelvic joints, should be avoided. When the patient is up and about a modification of the regular setting-up drill should be given, and if this is not made too long and too arduous, it usually will be carried out by the patient.

The amount of good that can be accomplished by the carrying out of the ideas suggested in this paper, of course, must be limited, but it is certainly true that if the possibilities which pregnancy opens up to the physician were more generally realized and appreciated, many women would be saved an immense amount of suffering and could possibly be started on the road to future improved health and strength.

## Reports of Societies.

### NEW ENGLAND PEDIATRIC SOCIETY.

Fourteenth Meeting of the New England Pediatric Society, held Feb. 25 in the Boston Medical Library.

Dr. John Lovett Morse in the chair.

The following papers were read:

(1) THE TRANSFUSION OF INFANTS WITH GLASS TUBES.

Beth Vincent, M.D., Boston.

(2) THE PUBLIC HEALTH LABORATORY.

B. L. Arms, M.D., Boston.

(3) DIARRHEA IN INFANTS ASSOCIATED WITH THE PRESENCE OF THE GAS BACILLUS IN THE STOOLS.[1]

Arthur I. Kendall, M.D., and Richard M. Smith, M.D., Boston.

Dr. Beth Vincent read a paper entitled,

THE TRANSFUSION OF INFANTS WITH GLASS TUBES,

In which he said:

The paper describes in detail the preparation and use of coated glass tubes in transfusing infants. The technic is based on experimental work carried out in the Laboratory of Surgical Research, Harvard Medical School. Tubes 12 cm. in length and 3 cm. in diameter at the ends are practical for the average newborn baby. The coating material consists of a mixture of vaseleur, paraffine and stearin in 2, 2 and 1 proportions. The paper includes the report of three cases successfully transfused by this method. In one case, the transfusion was done for post-operative hemorrhage; in the other two for hemorrhagic disease of the newborn.

DISCUSSION.

Dr. W. C. Quinby: It has been a great pleasure to have been able to help in a small way in this very interesting work of Dr. Vincent. It has convinced me thoroughly that from a practical surgical standpoint there is no other mechanical apparatus which will permit, with any fair chance of success, transfusion from the adult to a baby. The Crile or Elsberg apparatus are both inadequate, and even if one is exceedingly skilful in their use, I should say that the chances of success are relatively small, whereas with the tube method which Dr. Vincent has used the chances are distinctly in favor of a successful transfusion. Even when the procedure is made more easy by the use of tubes, experience and practice on animals is necessary in order to acquire familiarity with a method as minute as is this. Not only are the babies' vessels small, but they are in a position such as the groin which makes them very difficult to get at. I think that Dr. Vincent's work is especially commendable in having made transfusion, which we all know to be of value, also practical.

Dr. E. H. Risley: I would like to ask Dr. Vincent if he had any difficulty in using a tube which was straight and not flexible, because about a year ago I was doing some transfusion work and was attracted by an article by some New York men in which they described a preparation of carotid arteries of dogs. They took the small arteries out, strung them on two Crile canulas and straightened them out by means of a small silver wire and then preserved them in a weak 2% formalin solution and used them from time to time in transfusion. The preparation was very simple and they could be used as long as three or four weeks after preparation. They worked pretty well with the exception that the Crile canulas were most of them a little too large to accommodate the small carotid arteries of the dogs. This gave an extra length and the tube was a little bit flexible. If the tube is bent too much, the blood flow would not be as good. I wonder if Dr. Vincent found any difficulty because the tubes were straight.

Dr. C. P. Putnam: I would like to have Dr. Vincent tell us if he has any idea as to the amount of air which entered into the artery of the baby. It used to be held that even the smallest amount of air in a hypodermic syringe could cause an embolism. Also, does he know what amount of heat is necessary to sterilize these tubes by this method; whether the boiling of the wax would be considered sufficient. We must agree that

[1] Journal, March 2, 1911, page 306.

the observations and operations reported in his paper are of the greatest interest.

DR. W. P. LUCAS: One point which I think should be brought out is the importance in doing an operation like this of being acquainted with the experimental side of it, because I do not think that where one has not done the operation he can realize the minuteness and care which an operation of this kind requires.

DR. VINCENT: I should think that there would be distinct advantage in using the flexible tube, but the chance to do these transfusions came in my experience at longer intervals than six weeks and you have to have something to be practical surgically, that is, always available. I daresay that one who does a great many transfusions might be aided by their use. The greatest difficulty is in getting the tube into the small veins. We generally expect to unite the tube to the father's artery without much difficulty.

As far as the entrance of air was concerned, in the laboratory we disregarded it a great deal and did not have any trouble. The tube is very small and I do not imagine that it contains air. This is a point which I knew, from a surgical point of view, would be criticised, so I always fill them with salt solution.

In regard to the sterilization of the tube, it has been heated a great many times. Many of the tubes are not taken out of the box at all, and I am sure that the heat is sufficient to sterilize them, but I am not perfectly sure just what the temperature is, but in boiling I know that the temperature is carried above the boiling point of water.

DR. B. L. ARMS had a paper entitled,

### THE PUBLIC HEALTH LABORATORY.

### DISCUSSION.

DR. F. P. DENNY: I have been very much interested for the past twelve years in the problems to which Dr. Arms has referred, through my work in the Brookline Board of Health Laboratory, and there is just one matter in regard to the diagnosis of diphtheria that I should like to speak on. In a small laboratory where I personally know most of the physicians who send in the cultures, I hear more or less of the clinical side of the cases, and I see a fairly large proportion of the cases myself at the Board of Health Hospital. This has enabled me to get a fairly definite idea of the relation of the bacteriological diagnosis to the subsequent course of the disease. This experience has impressed on me the vital importance of making an early diagnosis and of giving antitoxin early. Some of the physicians always make cultures in suspicious cases and often give antitoxin without waiting for a report from the culture. As a result they seldom have a serious or fatal case unless the parent has neglected to call them in early. On the other hand, I regret to say, we see cases where the physician is called and makes no culture at his first visit. On the second day, as the case is then typical clinically, he makes the culture but waits for a report before giving antitoxin and then often gives too small an amount to be effective at that period Diphtheria is one of the few common medical diseases where promptness in diagnosis and treatment are vitally important. In many acute diseases, delay in diagnosis is of little consequence provided we keep the patient in bed. In this disease the responsibility of the physician is very great.

DR. ARMS: We always report if streptococci are present, but do not record other organisms in mixed cultures. We do whenever requested state what we find.

DR. J. L. MORSE: I should like to ask Dr. Arms just what the Board of Health is doing; how many different sorts of examinations they make, and how large a field they cover. In the examination of the sputum, do you examine for anything besides tubercle bacilli?

DR. ARMS: For the eleven months ending Dec. 31, we examined about 15,000 throat cultures, and slightly over 5,000 sputa, just over 2,000 typhoids, 191 smears from the eyes, 968 smears from the urethra, 340 glanders, 10 rabies, besides a good many other examinations classed under miscellaneous tests. In the sputum examinations we do not look for other organisms unless requested, although if streptococci are present this fact is reported.

The following discussion relates to a paper published in the JOURNAL, March 2, 1911, page 306, entitled

### DIARRHEA IN INFANTS ASSOCIATED WITH THE PRESENCE OF THE GAS BACILLUS IN THE STOOLS.

Dr. R. M. SMITH: I only want to reiterate what has already been said about the simplicity of the test. It takes no time to make up the media; the interpretation is extremely simple, and there seems no reason why it should not have a very wide application. It is only necessary to boil a little sterilized milk in a test tube to which has been added some fecal matter and at the end of twenty-four hours look at it, to see if the characteristic reaction is present.

DR. FRITZ TALBOT: This piece of work is of vast importance because it puts the treatment of the disease that we see so much of in the summer on a very definite and practical basis. This work and the work that was done on the dysentery bacillus is very interesting because it does not agree with what we are taught by the German school, and I congratulate the writers on their piece of work.

DR. T. M. ROTCH: I think that this is a very important communication and one that marks a decided advance in regard to diagnosis and treatment. I only hope that what has been stated will prove to be correct. I think it would be well not to simply speak of buttermilk in the treatment, but to state the special strain through which the buttermilk is produced. We know that there are a very large number of strains which will produce buttermilk, but perhaps only certain ones which may have a specific action on the bacilli producing the disease, such as has been indicated by Dr. Kendall. I merely mention this because a good many physicians have found that they have gotten no results whatever from the use of buttermilk. Now that we can pick out at least one organism which is affected by its use, we may go on and find others which will be affected in the same way.

It may, of course, eventually be proved that it is not an especial lactic acid bacillus which has a specific action on certain saprophytes, but that it is the acid medium produced by the bacilli which inhibits the special organism which is producing the intestinal disturbance.

DR. J. L. MORSE: After listening to this interesting paper there are a few questions which I should like to ask. In the first place, was the buttermilk which was used last summer in the treatment of these cases pasteurized or unpasteurized? To what do you attribute the action of the buttermilk; to a direct antagonistic action of the bacteria in the buttermilk on the gas bacillus, to the high acidity of the buttermilk, or to the fact that they are both organisms which live on sugars and that the lactic acid bacilli destroy the media so the gas bacillus cannot grow?

In giving the so-called buttermilk, I suppose it really was buttermilk which was made from skim milk, which consequently had a very low fat content, a moderate sugar and high proteid, the proteids being

very finely divided. Now the question comes to my mind, whether the low fat and rather low sugar content of the food may not have had something to do with its action.

Dr. C. W. Townsend: With regard to the gas bacillus, is there anything whatever that you can detect about the stools or symptoms that differ from those of the ordinary infectious diarrhea?

Dr. Kendall: I would like to say a word or two about the buttermilk which is now being placed on the market. Much of the ordinary buttermilk as it is delivered to the consumer consists of milk which has passed its usefulness, which has been sent back to the factory, pasteurized, lactic acid bacilli added and churned. After the removal of the butter fat, it is reintroduced to the trade under the guise of buttermilk. In addition to the lactic acid bacilli, which are supposed to be the principal agents, it also contains large numbers of putrefactive bacteria. These putrefactive bacteria may be so numerous that they actually overgrow the lactic acid organisms, and, instead of obtaining sour milk, one gets putrid milk. Buttermilk intended for therapeutic purposes ought not to be prepared in this way, but should be milk which is soured at the earliest possible moment and then introduced to the trade. Experience has shown that pasteurization does not necessarily kill the putrefactive organisms, and in the old milk referred to the subsequent introduction of lactic acid bacteria may actually fail to bring about the desired reaction in many instances.

The buttermilk used on the Floating Hospital was prepared by the Walker Gordon Laboratory and was unpasteurized and contained the bacillus bulgaricus.

There is apparently a distinct advantage in using buttermilk prepared by the method described in these cases of diarrhea caused by the gas bacillus. By using this soured milk it is possible to introduce immediately into the intestinal canal a certain amount of preformed lactic acid together with bacteria which can act upon the residual lactose of the buttermilk, thus maintaining a steady stream of lactic acid in the intestinal tract. We know that lactic acid is burned in the body, and if one relied exclusively upon the lactic acid present in the milk at the time of its administration, it is problematical how much lactic acid would be left by the time the milk reached the site of bacterial activity. By introducing together with the lactose these lactic acid bacilli we have in a measure a guarantee that the lactic acid will be maintained in at least a moderate concentration until the normal intestinal lactic organism can proliferate sufficiently.

The test consists of inoculating sterile whole milk with a small amount of the fecal material and either heating the resulting mixture to 80° C. for twenty minutes or bringing the mixture to the boiling point of water in a water bath, and maintaining it at this temperature for three minutes. If sterile, whole milk is not available in emergencies; the test can be made by using certified milk instead of a sterile milk. Ordinary market milk would be unsuitable for this test unless it were sterilized because not infrequently such milk contains gas bacilli. It must be apparent that the most reliable results will be obtained through the use of sterile milk.

There are a great many different strains of lactic acid bacilli in use at the present time for preparing sour milk. Certain of these organisms, and notably the bacillus bulgaricus, have been grown in milk so long that they have actually become what might be termed milk bacteria. Furthermore, these organisms have been used for generations in certain oriental countries for the production of sour milk for human consumption and it is fair to assume that the use of these organisms prescribed rationally would probably lead to no harm. On the other hand, the mere fact that an organism produces lactic acid is no guarantee that it would be a useful one for introduction into the intestinal tract, and it would seem that the careless use of cultures which have not been subjected to careful scrutiny to determine their fitness for therapeutic purposes is to be deplored. If the learned doctor from Sweden, — I do not remember his name, — has used buttermilk indiscriminately, it is hardly to be wondered at this his results were so unsatisfactory. Experience in the past has shown that buttermilk is of benefit only in a rather limited and probably circumscribed type of intestinal disturbance. Buttermilk cannot by any means be regarded as a universal therapeutic agent.

## Book Reviews.

*A Practical Guide to the Newer Remedies.* By J. M. Fortescue-Brickdale, M.A., M.D. Oxon. New York: William Wood & Co. 1910.

This volume is a review, not of patent medicines or secret remedies, but of "the newer drugs (mainly the products of synthetic chemistry), the composition of which is published and whose pharmacology has been more or less accurately ascertained." These are presented under eight groups, and their administration and therapeutic value carefully discussed. The book should be useful to internists and general practitioners.

*Personal Hygiene and Physical Training for Women.* By Anna M. Galbraith, M.D. Illustrated. Philadelphia and London: W. B. Saunders Company. 1911.

This volume is an admirably written textbook on the hygiene and physical training of women, adapted not only for teachers, students and graduate nurses, but for individual use in the home as well. It contains an excellent series of plates, illustrating physical and dancing exercises, and a description of the outdoor sports best suited to women. Its appearance is a wholesome sign of modern progress and it should aid in the establishment of sensible ideals of physical culture.

*Remedial Gymnastics for Heart Affections.* Being a translation of "*Die Gymnastik der Herzleidenden*" von Dr. Med. Julius Hofmann and Dr. Med. Ludwig Pöhlman. By John George Garson, M.D. Edin. With 51 full-page illustrations and diagrams. New York: Paul B. Hoeber. 1911.

This English translation of a German work presents the system of gymnastic exercises employed in cardiac cases at Bad-Nauheim. The first portion describes the indications for their use and the methods of testing and controlling their results. The second describes the exercises, 8 active and 20 passive, and is illustrated by an excellent series of plates. The system deserves study by all who are concerned with the mechanotherapeutics of cardiac disease.

*An Introduction of Surgery.* By Rutherford Morison, M.A., M.B., F.R.C.S. Edin. and Eng., Professor of Surgery, University of

Durham College of Medicine, Newcastle-upon-Tyne; Senior Surgeon to the Royal Victoria Infirmary. With 146 illustrations in the text and 5 colored plates. New York: William Wood & Co. 1911.

Here is a little book in octavo of 162 pages, with five supplementary colored plates. The writing is purposely elementary; it is inevitably fragmentary, but it is suggestive and informing for both lecturers and students. It is well written, effective and good. As the author says, his chief object in lecturing is to emphasize the importance of general principles, and his purpose in writing this book is to provide a supplement to, not a substitute for, the standard textbooks. The book is divided into ten topics or chapters, — Inflammation; Bacteria; Ulcers; Gangrene; Syphilis, Tubercle and Malignant Disease; Hemophilia; Wounds; Abdominal and Pelvic Viscera; Indications for Operation, and X-Rays. All of these topics, though briefly treated, are discussed cogently. We believe that the book should prove of great assistance to the second or third-year student at the outset of his course in surgery. He should read it and assimilate its teachings in a week.

*A Handbook of Practical Treatment.* By Many Writers. Edited by JOHN H. MUSSER, M.D., LL.D., and A. O. J. KELLY, A.M., M.D. In three volumes. Volumes I and II. Philadelphia and London: W. B. Saunders Company. 1911.

Under the modest title of "handbook," this elaborate work in three large octavo volumes presents the contributions of seventy-nine experts in special departments of medicine to a complete system of practical therapeutics. Such a symposium, representing the opinions and experiences of so many individuals over so wide a range of subjects, cannot help varying in merit and inevitably lacks the unity of a book by a single author. It, however, has the advantages of its defects and makes up in breadth of treatment and variety of standpoint for what it lacks in singleness of conception. Its several divisions deserve some detailed consideration.

The first volume deals with the general, fundamental principles of therapeusis and of prophylaxis; with diet in infancy, childhood and adult life; with drug therapy, serum therapy, organotherapy and the various physical and mechanical methods of treatment; with the treatment of the intoxications, including drug poisonings and addictions, insolation, food intoxication and poisoning by reptiles and insects; and finally with the treatment of diseases of the blood, the lymphatic system and of the ductless glands. In the way of criticism, discrimination runs the risk of being invidious. Of especial merit and interest, however, seem the chapters on dietetics, on diseases of the blood, and on the surgical treatment of diseases of the thyroid and parathyroid glands. The illustrations, though not many, are excellent. Particularly to be commended are those in the sections on massage, mechanotherapy and hydrotherapy.

The second volume takes up the treatment of diseases of the circulatory system, including cardiac surgery; of the infectious diseases; and of tropical diseases and diseases due to animal parasites. There are special chapters on the ocular, aural and joint complications of the infectious diseases, and on the surgical complications of typhoid fever. The chapters on rubella, madura foot, and foot-and-mouth disease have the merit of brevity; but that on actinomycosis might to advantage be more extended. The chapter on tuberculosis perhaps deserves particular commendation for its completeness and excellence of illustrations.

The third volume of this work, which has not yet appeared, will complete the consideration of diseases of the remaining systems of the body.

That there should be a certain amount of repetition is inevitable in a work of such magnitude and with such variety of authorship. The fields of medicine are not sharply bounded, but overlap each other; and consideration of the same topic from different aspects is often helpful and advantageous. To the editors of the book belong much credit for the system and harmony of the whole. The chapters on special diseases of necessity contain brief introductory statements of etiology, pathology and diagnosis, but these have been reduced to the minimum essential for an understanding of the discussion of treatment. On the whole the editors seem to have shown the greatest judgment in the arrangement and coordination of the work; and have given to the medical profession an admirable compendium of the best modern expert knowledge in the treatment of human disease.

*Pulmonary Tuberculosis and Sanatorium Treatment.* A Record of Ten Years' Observation and Work in Open-Air Sanatoria. By C. MUTHU, M.D., M.R.C.S., L.R.C.P., Associate of King's College, London; Physician, Mendip Hills Sanatorium, Wells, Somerset; late Physician, Inglewood Sanatorium, Isle of Wight. New York: William Wood & Co. 1910.

This book consists of a series of essays on tuberculosis. It is divided into three parts. The first deals with some of the scientific aspects of the subject in which the author gives expression to strange views. Sweeping aside the truths of bacteriology, he calmly asserts without a shred of evidence that tubercle bacilli may be formed in the body from harmless saprophytes if "the soil" is favorable. The second part of the volume is devoted to the sanatorium treatment, and the third and concluding division to social and economic factors concerned in the production of tuberculosis.

In addition to the open-air treatment, the author advocates formaldehyde inhalations and static electricity.

The book is well printed and well illustrated.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, JUNE 8, 1911

*A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.*

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

*All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston.*

*All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.*

*Remittance should be made by money order, draft or registered letter payable to*

W. M. LEONARD,
101 TREMONT STREET, BOSTON, MASS.

## RESTORATION OF THE ARMY CANTEEN.

THERE is at present pending before the National Congress a bill for the restoration of the army canteen. This bill has met with considerable opposition from the same elements originally instrumental in obtaining the abolition of the canteen, and it seems opportune to consider briefly the results of this abolition as bearing on the question before Congress.

The canteen system in the United States Army was abolished in 1901, under the argument that its suspension would conduce to sobriety and good conduct among the soldiers. As a matter of fact, precisely the opposite seems to have been the result. In an article on "Army Morals and the Canteen," in the *North American Review* for March, 1911, Mr. James H. Blount points out that the effect of abolition has been to drive troops from the canteen, where they obtain pure beer and malt liquors under respectable environment and oversight, to saloons, where they get bad spirits under disreputable surroundings and without supervision. The testimony of commanding generals in the army is unanimous upon this point. In consequence there has been an increase in the army not only of drunkenness and disorderly conduct arising therefrom, but in the incidence of venereal disease. In his report for 1904, General Chaffee, then at the head of the army, made the following emphatic statements on this subject:

"The canteen provided places of amusement and social intercourse, where men could get light refreshments under restraining, decent and orderly influences.

"If men are unable to get a glass of beer in a decent and orderly manner in the garrison, they will resort to the vile brothels which cluster around the borders of the reservations, where they drink all manner of alcoholic beverages and often sink into debauchery and ruin.

"With the beginning of the work on the addition to the post of Fort Sam Houston it is observed that the prices of business property immediately in the rear of the new reservation have materially advanced and that arrangements are already being made for the construction of the usual assortment of saloons and dives that the virtual abolition of the canteen feature of the post exchange has made a universal accompaniment of every military post.

"I think it is beyond question that permission to sell beer in the post exchange would drive out of business at least two thirds of the lower resorts in the vicinity of posts."

Similar statements relative to the results of abolishing the canteen have been made by army medical officers. In his report for 1907, the Surgeon-General of the army says:

"This office concurs in the opinion expressed by most medical officers of the army that the abolition of the sale of beer in the post exchanges has had much to do with the increase of venereal diseases and alcoholism in the army by driving the soldiers to disreputable resorts outside of the post and beyond control of the post authorities."

As a matter of fact, in the decade from 1888 to 1897, when the canteen was in operation, the mean annual rate of admission to hospital for venereal disease among army soldiers was 7.5%. In 1901 this figure rose to 15% and in 1909 it was 20%, a number far in excess of that obtaining in the army of any other civilized nation. The rate of admission for this cause in the British Army is 7.6%, in the French Army 3.5%, and in the Prussian Army 1.9%. The significance of these facts is great. It is not that the individual soldiers of these nations are intrinsically more virtuous or continent than our own, but that they are more considerately safeguarded from temptations which they are unaccustomed to resist. The canteen may have induced a few men to drink beer who otherwise would not have done so, but it has induced many more to keep away from the hard liquor and gambling of the saloon; and its abolition has apparently led to a great increase of venereal disease in the army.

After ten years of such abolition these results should be efficient arguments for the restoration of the army canteen. The canteen is the soldier's club, where he can obtain beer and soft drinks, meet his comrades socially, play games and read magazines under decent conditions. Its alternative is the saloon, where he drinks bad whiskey and meets questionable associates of both sexes.

The consequences are obvious. The abolition of the canteen was a mistake, but, like many other errors, will perhaps have been worth while if its results serve to teach the community a sensible attitude towards the liquor question. Doubtless abstinence from alcohol is a wise virtue, and it should be fostered among soldiers by education and by the encouragement of temperance organizations. But it should be remembered that the practice of abstinence from liquor and other evils is not likely to develop more rapidly in the army than in the community at large.

"Single men in barricks
Don't grow into plaster saints."

The desirable thing is to keep them in barracks and not send them where their growth in sanctity will be still more rudely inhibited. The young soldier offers his life for the service of his country and has a right to demand that that life and its welfare shall be judiciously protected and not exposed to needless peril.

For these and other reasons it is sincerely to be hoped that the bill for restoration of the army canteen will be passed. A petition in its favor, signed by two hundred prominent physicians in civil practice throughout the country, has been presented to Congress. We believe that favorable action on this bill will prove conducive to the best interests of temperance, morality and health in the United States Army.

## PROBLEMS OF THE MILK SUPPLY.

IN the issue of the JOURNAL for May 25 we published a note describing the milk exhibit then in progress at Philadelphia. This exhibit closed on May 27, after a most successful week, with an average of 15,000 visitors daily. At the meetings of the several societies under whose management it was held, numerous papers were presented, among them one by Dr. Milton J. Rosenau, of Boston, president of the American Association of Medical Milk Commissions, on "The Pasteurization of Milk," and one by Dr. Nelson C. Davis, of Dorchester, Mass., on "Certified Milk."

The problem of milk supply is one of the most vexing of those that now beset public sanitarians, and one whose solution offers great difficulty in doing justice to all concerned. In this connection reference may be made to the recently published report of a special committee appointed by the Washington Chamber of Commerce to investigate the milk situation in the District of Columbia. This report was transmitted to the United States Senate Committee on the District of Columbia, and is printed as a Senate document (No. 863). It deals *in extenso* with the various evils associated with the milk traffic, presents the history of federal and local regulation of milk supply, discusses pasteurization, refrigeration, the use of the tuberculin test and the determination of bacterial content of milk, comments on infant feeding, the care of milk in the home, prepared milks and milk products, and finally presents a series of fifty-nine recommendations based on its findings and conclusions. In short, it affords a thorough and careful exposition of various aspects of the milk problem, applicable not only to Washington, but to all large urban communities. With its extensive appendices, it constitutes a valuable document deserving of study by those concerned in the equitable and salutary regulation of the milk business in Boston and in other cities. An exhibit such as that recently held in Philadelphia is also a most efficient mode of arousing public interest in the question and should lead to the demonstration of efficient methods of production, transportation and distribution, which may well be adopted elsewhere.

## HOURS OF WORK FOR NURSES.

IN the issue of the JOURNAL for May 25 we published a preliminary announcement of the seventeenth annual meeting of the American Society of Superintendents of Training Schools for Nurses, which was held in Boston on May 29, 30 and 31. In addition to the addresses mentioned in this note, others of interest and importance were made by Dr. Richard C. Cabot, Dr. William M. Conant and Dr. Thomas F. Harrington. The fourteenth annual meeting of the Nurses' Associated Alumnæ was held during the same week, and on June 1 a reception to visiting nurses was given by the Boston Instructive District Nursing Association.

Among the subjects discussed at the sessions was that of the number of hours' work that should be required daily of nurses. There seemed to be a general opinion that the twelve-hour day of service is not only arduous, but imposes an injurious tax on the strength and efficiency of nurses, and that an eight-hour day, with three reliefs, should be substituted therefor. In hospitals and training schools this is possibly true, and probably in time a reduction of the hours of compulsory routine work will mitigate the hardships of life in such institutions and prevent injustice and physical detriment to the individual.

In private work and in times of exigency, however, no nurse who is worthy of her calling will forget that one of its privileges, which places it with that of the physician on a level above the mere manual occupations, is the privilege of working beyond hours and without stint in the service of others. There will doubtless always be women who will rise to this sense of their privilege and responsibility. Experience, however, shows that this is by no means universally the fact, and that a tendency even is discernible, which should at least be seriously considered by those interested, that a granting of privileges may be carried too far. In private nursing, stipulation of hours, as of other matters relating to the care of the patient, may well be allowed to remain without special regulation. As suggested above, no injustice will be done if the same principles are made to apply to the nurse as to the physician.

## PURE FOOD LAW COVERS THE INGREDIENTS, NOT THE VIRTUE OF CONTENTS.

In the issue of the Journal for April 20 we noted the trial before the United States Supreme Court at Washington, D. C., of an appeal in the case of Dr. O. H. Johnson, of Kansas City, Mo., relative to the right of a manufacturer under the pure drug law to label a medicine with statements relative to its supposed or alleged curative properties. On May 29 the court rendered a decision sustaining the original verdict of the District Court in Missouri. In the opinion of the court the pure drug law applies only to statements as to the ingredients of contents, not to asseverations as to their virtue. If the statement on a box or bottle of medicine be "shown to be false only in its commendatory and prophetic aspect," such statement cannot be inhibited under the provisions of the law. This case marks the final establishment of an important precedent. Hereafter the pure drug law can be construed only with regard to statement of facts, and the gullible public must protect itself by its own discretion against the therapeutic claims of patent medicines and advertised alleged "cures" for the ailments of the flesh.

## MEDICAL NOTES.

Plague and Smallpox at Amoy. — It is reported in the daily press that during the fortnight ending June 2 there were 54 deaths from the bubonic plague, and 7 from smallpox, at Amoy, China.

Appointment of Dr. Swingle. — It is announced that Dr. L. D. Swingle, of the Nebraska Wesleyan University, has been appointed research parasitologist at the Wyoming Agricultural Experiment Station.

A Centenarian. — Samuel Putnam, who died last week at New Salem, Mass., was locally reputed to have been born in 1807. He is survived by one son, by two grandchildren (one of them a physician), and by three great-grandchildren.

Injury to Prince Joachim. — It is reported from Berlin that during the military maneuvers of the Second Guard Brigade, on May 29, Prince Joachim, Emperor William's youngest son, was accidentally injured, sustaining a fracture of one of the bones of the foot.

Yellow Fever Aboard a French Steamer. — A press despatch from Fort de France, Martinique, states that on May 29 the French steamer *Perou* was quarantined at that port, having had on board, during her voyage from the Isthmus of Panama, 15 cases of yellow fever, with 2 deaths.

Croonian Lectures for 1911. — It is announced from London that the annual Croonian lectures before the Royal College of Physicians of London will be delivered on June 13, 15, 20 and 27, by Dr. Henry Head, F.R.S., on "Sensory Changes from Lesions of the Brain."

Association of American Physicians. — At a meeting of the Association of American Physicians, recently held in Atlantic City, N. J., the following officers were elected for the ensuing year: President, Dr. J. George Adami, of Montreal; Vice-President, Dr. Lewellys F. Barker, of Baltimore.

Reported Successful Corneal Graft. — Report from Paris on May 28 states that at a recent meeting of the French Ophthalmological Society, Dr. Borsch, an American oculist practicing in that city, read a paper describing the successful transplantation of a portion of dog's cornea into the eye of a patient blind from ophthalmia.

A Distinction for Professor Pickering. — Report from Berlin states that on May 31 the German emperor conferred the Prussian Order of Merit upon Edward Charles Pickering, S.D., Ph.D., LL.D., director of the Harvard Observatory and Paine professor of practical astronomy in Harvard College. This order has two civil

departments, one of science and one of fine arts. Prof. Louis Agassiz and Prof. Simon Newcomb are the only other Americans who have received this distinction in the department of science.

AMERICAN ASSOCIATION OF GENITO-URINARY SURGEONS. — At the twenty-fifth annual meeting of the American Association of Genito-Urinary Surgeons, held at New York City, May 31 to June 3, 1911, the following officers were elected for the ensuing year: President, Dr. Edward Martin, of Philadelphia; Vice-President, Dr. Edward L. Keyes, Jr., of New York; Secretary and Treasurer, Dr. J. Bentley Squier, of New York; Members of Council, Dr. Charles L. Gibson and Dr. Robert H. Greene, of New York. Philadelphia was selected as the next place of meeting.

TOLERANCE OF ANIMALS FOR SNAKE VENOM. — In an editorial in the issue of the JOURNAL for Dec. 1, 1910, we commented on the high degree of immunity to snake venom possessed by the hedgehog. Experiments recently recorded by Billard and Maublant in the *Comptes Rendus* of the Biological Society of Paris indicate that the owl, the duck and the domestic cat are similarly immune to the venom of vipers. The idiosyncrasy and tolerance of various animals for different poisons is one of the singular phenomena of comparative physiology.

DEGREE OF D.P.H. AT UNIVERSITY OF MICHIGAN. — It is reported that a special medical course leading to the degree of Doctor of Public Health is to be established at the University of Michigan. The course will be of two years' duration and will be open to graduates of reputable medical schools. The work will be divided equally between preventive medicine and sanitary engineering. The purpose of the course is to train physicians to serve on municipal health boards and in other positions as public hygienists.

A PROJECTED WORK ON TROPICAL SURGERY. — The College of Medicine and Surgery of the University of the Philippines has issued a circular letter announcing its intention of issuing a publication on "The Surgery of Tropical Diseases," and requesting contributions of data therefor from the personal observation and experience of physicians who have lived and studied in the tropics. There follows a list of fifty-three topics upon which information is specially requested; for instance, the infrequency of prostatic hypertrophy among native Filipinos, which appears to be very noteworthy. It is to be hoped that ample contributions may be made by those qualified, in order that this projected work may fulfill its promise of excellence and completeness.

HEALTH OFFICERS' ASSOCIATION OF NEW JERSEY. — At a meeting held in Newark, N. J., on May 24, the Health Officers' Association of New Jersey was formally organized and its constitution adopted. Thirty-three members and several guests were present. The purposes of the association are "the advancement of knowledge relating to public health and the promotion of social intercourse among health officials." There are to be five regular meetings each year. The active membership is to consist of employees of the state and local boards of health. Members of these boards are eligible to associate membership.

## BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, June 6, 1911, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 85, scarlatina 26, typhoid fever 9, measles 156, smallpox 0, tuberculosis 76.

The death-rate of the reported deaths for the week ending June 6, 1911, was 15.97.

BOSTON MORTALITY STATISTICS. — The total number of deaths reported to the Board of Health for the week ending Saturday, noon, June 3, 1911, was 213, against 213 the corresponding week of last year, making the death-rate for the week, 16.12. Of this number 114 were males and 99 were females; 204 were white and 9 colored; 138 were born in the United States, 74 in foreign countries and 1 unknown; 39 were of American parentage, 142 of foreign parentage and 32 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 60 cases and 2 deaths; scarlatina, 26 cases and 2 deaths; typhoid fever, 5 cases and 0 deaths; measles, 166 cases and 4 deaths; tuberculosis, 70 cases and 14 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 26, whooping cough 4, heart disease 16, bronchitis 2. There were 19 deaths from violent causes. The number of children who died under one year was 40; the number under five years, 60. The number of persons who died over sixty years of age was 51. The deaths in hospitals and public institutions were 95.

A Death from Anthrax at Lynn. — A fatal case of anthrax at the Lynn Hospital was reported last week from Lynn, Mass. The patient was a morocco worker who had recently moved to that city from Peabody, Mass.

Diphtheria in Boston. — Twenty-five cases of diphtheria are reported to have occurred in Boston last week. A special investigation of the source of this outbreak is being made by the Boston Board of Health.

Smallpox in Two Massachusetts Towns. — Report from Oxford, Mass., states that on May 31, 3 cases of smallpox were discovered in that town in a family that had recently arrived from Seattle, Wash.

One case of smallpox was also reported last week in Wakefield, Mass.

National Conference of Charities and Correction. — The thirty-eighth annual meeting of the National Conference of Charities and Correction is being held this week in Boston. It is estimated that two thousand delegates will be in attendance at its sessions and at those of various affiliated organizations which meet at the same time. Among the latter is the American Red Cross. President Eliot will deliver an address on "Education in Sex Hygiene." Other topics to be considered are juvenile delinquency, the suppression of tuberculosis, and the care of the insane.

Work of the Berkeley Infirmary. — At a meeting held in Boston last week in the interests of the Berkeley Infirmary, addresses were made by President Charles W. Eliot, Dr. Benjamin Tenney and Dr. John W. Dewis. The directors of the institution reported that during the year 1910, 4,594 old cases and 813 new cases were treated at the Medical Department of the Infirmary, and 974 patients were visited at their homes. In the Dental Department 668 patients were treated, of whom 223 were new cases. It is desired by the directors to raise a considerable sum of money for the equipment of a new operating room.

Massachusetts Medical Society. Demonstrations and Tea at Tufts College Medical School. — The Faculty of Tufts College Medical School extend a cordial invitation to the members of The Massachusetts Medical Society to visit the school building, Tuesday, June 13, from four to six o'clock P.M., during which time tea will be served.

There will be demonstrations in the departments of Pathology, Chemical Pathology, Pharmacology, Histology and Physiology. These demonstrations will consist of laboratory teaching methods and various exhibits.

There will also be a demonstration of the Leitz Kaiserling projection apparatus; opaque projection, including upright objects; lantern slide projection; microscopical projection; moving objects; stained sections; direct x-ray projection.

Dr. Arial W. George will exhibit a series of x-ray plates projected directly on the screen.

### NEW YORK.

Bequest to St. Luke's Hospital. — By the will of the late Mrs. Catherine E. Daly, of New York, the sum of $10,000 is left to St. Luke's Hospital to establish two beds in memory of her husband, Henry F. Daly, for the benefit of "dramatic, minstrel, variety and circus performers," one for a man and the other for a woman.

Appointment of Dr. Connolly. — Dr. Walter H. Connolly has been appointed first deputy medical superintendent of Bellevue and Allied Hospitals, to succeed Dr. George O'Hanlon, who is now promoted to the position of general medical superintendent. Dr. O'Hanlon has served for eight years on the staff of the Buffalo State Hospital for the Insane and four years on that of the Albany City Hospital.

Election of Dr. Newcomb. — On May 31 Dr. James E. Newcomb, of New York, was elected president of the American Laryngological Association, at its annual meeting held in Philadelphia. Dr. Newcomb is consulting laryngologist to Roosevelt Hospital and is prominently identified with the Stony Wold Sanatorium in the Adirondacks for incipient tuberculosis in young women and girls, of which Mrs. Newcomb is president.

Beth David Hospital. — The Federation of Russian Polish Hebrews of America has purchased a city block on 86th Street, near the East River, for a new building for the Beth David Hospital. This will be 90 by 72 feet and six stories in height, and will have a capacity of 150 beds. The Beth David Hospital is the successor of the Yorkville Hospital, an institution established for some time on East 82d Street, and its present quarters, with only 30 beds, are inadequate to its needs.

REGULATION OF COLD STORAGE. — The Brennan bill regulating the cold storage business of the state, which was passed some time ago by the lower house of the Legislature, has now been passed by the State Senate and will no doubt be approved by the governor. Some slight alterations were made in the bill after the Senate committee on public health made a personal inspection of several of the large cold storage plants. By the provisions of the act the State Health Department is vested with authority to supervise all such plants, and the period during which articles of food may be kept in cold storage is limited to ten months, except in the case of butter, which may be kept for twelve months.

PROJECTED OSTEOPATHIC HOSPITAL. — It is reported that the osteopaths are planning to build a hospital in Manhattan and establish a clinic in Brooklyn, for which purposes a wealthy resident of the city, whose name has not been disclosed, is said to have offered the sum of $1,000,000. It is further stated, however, that these institutions will not be started until the litigation between the osteopaths and the city Health Department has been finally settled. The latter having refused to accept certificates of death from these irregular practitioners, the matter was taken to the courts, and recently the Appellate Division of the New York Supreme Court sustained the action of the lower court, which upheld the contention of the department. The osteopaths are now going to take their case to the highest tribunal in the state, the Court of Appeals, and if, as is likely, the decision there also is against them, it would seem probable that they will abandon their hospital plans.

MORTALITY STATISTICS FOR MAY. — The weekly reports of the Health Department show that during the month of May the mortality in the city represented an annual death-rate of 16.09, as against 17.54 in April and 15.61 in May, 1910. Among the diseases in which there was a decline in fatality were the following: The weekly average of deaths from scarlet fever decreased from 32.25 in April to 28 in May; the weekly average from influenza, from 11.25 to 9.25; from pulmonary tuberculosis, from 195.75 to 186.5; from acute bronchitis, from 22.25 to 19; from pneumonia, from 172.25 to 109.25; from bronchopneumonia, from 146.75 to 110.5; from diarrheal diseases, from 63 to 61.75; from diarrheals under five years of age, from 58 to 50.5; from apoplexy and softening of the brain, 28.25 to 20.5; from organic heart diseases, from 158.75 to 157.5; from appendicitis and typhlitis, from 14.75 to 12.5; and from Bright's disease and acute nephritis, from 124.75 to 100.75. Among the diseases in which there was an augmented mortality were the following: The weekly average of deaths from measles increased from 17.5 to 26; from diphtheria and croup, from 34.75 to 36.5; from cancer, from 70.5 to 76.25; and from puerperal diseases, including septicemia, from 13.5 to 17.75. With the advent of mild weather, there has been the usual decline in the mortality from respiratory diseases. Measles is unusually prevalent for so late in the season, and during the week ending May 20 there were 39 deaths from it. That week 1,368 cases of the disease were reported, and the week following, 1,459. During the month there were an unusually large number of deaths from malarial diseases, 8. Ordinarily, only one or two deaths are reported from this cause.

INCREASE OF INFANT MORTALITY. — The records of the Health Department show the rather disquieting fact that during the first four and a half months of the present year the death-rate in the city among children under the age of two years, from intestinal diseases, was nearly one third greater than in the same period of 1910. In this period in 1910 there were 709 deaths, and in 1911, 947 deaths, an increase of 32.2%. The principal cause of this increase at a time of the year when infant mortality is usually at about its lowest point is attributed by the New York Milk Committee of the Association for Improving the Condition of the Poor to the use of "loose" milk. By this is meant milk kept on sale in large cans, such as is dispensed by corner grocerymen and other retail dealers. It generally remains in the cans for a very considerable time, so that it becomes stale and loaded with an enormous number of bacteria. It may perhaps be the case that this year the percentage of humidity in the atmosphere, which naturally favors the development of bacteria, has been unusually high. It is, of course, a well-established fact that the mortality among breast-fed infants is always much less than in the artificially fed, and the milk committee's sub-committee on the reduction of infant mortality, of which Dr. Pisek is chairman, has ascertained that of the infants who died last year in New York from intestinal ailments, only 5% were breast fed. It is also believed that the low water in the city's reservoirs, in consequence of the small rainfall, may have had something to do with the increased mortality this

year, for while the numerous vegetable organisms the water contains are harmless to mature persons, they are no doubt more or less injurious to infants. Another cause of the increase has been found in the increasing practice of having young babies treated by ignorant midwives instead of by physicians, this being especially the case among the foreign population. Very commonly these women soothe the infants with narcotic drugs, and thus lower their vitality. The investigation has shown that the death-rate was unusually high in some infant asylums, especially those which farm babies out. In certain of these institutions the death-rate was as high as 68%, while in others, where special attention was paid to the quality and care of the milk used, or where the committee had established its own pure milk depots, the death-rate was considerably less than half this. In addition to its work in establishing and maintaining sixty milk stations for the summer, at a cost of $300,000, with a view to diminishing the infant mortality, the committee is exerting itself to have passed a municipal ordinance along Health Commissioner Lederle's graded-milk plan. Such an ordinance would provide that all milk sold in the city should be divided into grades and labeled according to its quality: as, for instance, "babies' milk," "drinking milk," "cooking milk."

1. Fetterolf and Norris have collected 37 cases of mitral stenosis with left recurrent laryngeal paralysis, 11 with autopsies. The anatomical explanations of the paralysis offered by different authors have varied so widely that a special study of the anatomic relations in hardened thoraces was made. As a result of this study it is concluded that where compression is the cause of the paralysis it must be between the left pulmonary artery and the aorta or the aortic ligament. Compression between a dilated left auricle and the aorta is shown to be impossible.

2. Minor and Ringer have tested Arneth's method of blood counting as a basis for prognosis in pulmonary tuberculosis and report that they have found it distinctly helpful. The method is based upon the belief that young leucocytes with one or two nuclei are less able to combat infection than older leucocytes with more nuclei, and that patients in whose blood the proportion of leucocytes with many nuclei is large are more resistant to disease than those whose leucocytes contain relatively few nuclei. A count is, therefore, made in a stained smear dividing the neutrophilic leucocytes into five classes according to the number of their nuclei: Class I, containing one nucleus; Class II, two; and Class V, five. The normal blood picture obtained by Arneth from fifteen normal individuals was as follows: Class 1, 5%; Class II, 35%; Class III, 41%; Class IV, 17%; and Class V, 2%. An example of an unfavorable blood picture is furnished by a case of miliary tuberculosis in which the figures in Classes I and V were 36%, 56%, 8%, 0%, 0%. Minor and Ringer have studied in this way a hundred cases and report their results in tables and in a graphic chart showing a marked increase in the proportion of leucocytes with few nuclei according to the severity of the case. Instances are cited where the test proved correct, contrary to the opinion at first formed of the case.

3. Morgan reports favorably upon the use of Einhorn's so-called thread test in the diagnosis of gastric and duodenal ulcer. He applies the test as follows: A split BB

shot is fastened to the end of a No. 8 braided silk thread and enclosed in a 5-gr. capsule, the cord passing out through a small hole in one end; 75 cm. from the capsule a knot is made. For several hours before the test, care is taken not to give foods or medicines which might discolor the thread, particularly meat. At bedtime the patient swallows the capsule until the knot is at the teeth, when the end is pinned to the nightgown. On awakening, the patient pulls out the thread and hangs it up to dry. In cases of ulcer a reddish-brown discoloration is seen on the thread where it has been in contact. Twenty-five cases are reported. Of the 16 cases of undoubted ulcer, 14 gave positive reactions; of 6 cases certainly not ulcer, none gave a positive test.

4. Hirshberg reviews briefly and somewhat disconnectedly the subject of anaphylaxis or sensitization of the animal body by an earlier injection of a serum or other substance toward toxic effects of later injections of the same substance. Without clear statement of evidence he implies his belief that skin eruptions from ingestion of certain foods are manifestations of this phenomenon.

5. Williams reports strikingly beneficial results in eight cases of pyorrhea alveolaris treated with autogenous vaccines. Treatment of other cases with stock vaccines was less satisfactory.

6. Ranson and Scott contribute an important article based upon a study of a large series of cases of delirium tremens, divided into two classes, the incipient cases without actual delirium, and the fully developed cases with delirium. The distinction between these two classes is important from its bearing upon treatment. Hypnotics are first discussed. These in general appear to be of benefit in the incipient cases but to be worthless or harmful in the delirious cases with the exception of veronal. Morphine and hyoscine in these cases proved the least efficient in preventing delirium, and hyoscine further proved very dangerous. Experience with alcohol seemed to show that its use in incipient cases tended to ward off delirium but that in fully developed cases alcohol neither increased nor diminished the mortality. In delirious cases ergot is said to have reduced the mortality from 44% to 28% — a dram of the fluid extract by mouth every four hours being the usual dosage. They conclude that incipient cases should receive large doses of veronal, whisky regularly, and ergot at frequent intervals; that delirious cases should receive veronal in moderate doses and ergot.

7. Pilcher, by animal experiment, reports the demonstration of duodenal secretion of considerable amount, increasing in digestion and alkaline in approximately the same degree as the gastric juice is acid. He maintains that the pain in duodenal ulcer is due to contact of acid with the ulcerated surface, and that this alkaline duodenal secretion is the natural agent for neutralizing acidity in the duodenum.

8. Schwartz and McNeil report the results of complement fixation tests in 324 sera with an antigen prepared by the use of many different strains of gonococci. They conclude that in performing the test with this antigen a positive reaction is obtained wherever any one of the component strains is present. Thus by one test one obtains a positive reaction in the great majority of gonococcal infections. Sixteen control sera all proved negative. Sera from cases of simple acute anterior gonorrheal urethritis also proved negative. Clinically cured cases of gonococcus infection gave reactions in some cases, but in a larger proportion did not. Without considering the question decided, the belief is expressed that a positive reaction means that there exists a focus of living gonococci somewhere in the body.

9. Bailey reports a case where a venous pulse, believed to have been due to tricuspid regurgitation, was present in a varix of the leg.

10. Harris urges closer attention to the diagnosis of pellagra and raises the question whether there are not cases in which the skin eruption is not observed but which are nevertheless cases of the disease.

11. Crane's method of determining the opsonic index deserves attention from those who practice this test. By means of a rotating apparatus made from the works of a clock the washing of corpuscles is dispensed with. The process, however, does not appear to increase the accuracy and reliability of the procedure. [F. W. P.]

ARCHIVES OF INTERNAL MEDICINE.

4. Hattrem and Hawk made a physiological study of the effect of water drinking on intestinal putrefaction. They find that the drinking of copious volumes of water with meals decreases intestinal putrefaction as measured by the urinary indican output. Moderate amounts of water with meals produced a less pronounced decrease. This decrease is probably due to a diminution of the activity of indol-forming bacteria following the accelerated absorption of the products of proteid digestion, and the passage of excessive amounts of strongly acid chyme into the intestine. In copious water drinking the writers found that the total ethereal sulphate output was increased coincidently with the decrease in indican. This observation favors the view that indican has an origin different from that of the other ethereal sulphates, and that they cannot correctly be considered as indices of the same metabolic process.

5. Winternitz, Henry and McPhedran report on an elaborate clinical study of the catalytic activity of the blood. They investigated the blood of seventy patients suffering from internal diseases. They point out that the oxygen-carrying power of the blood cannot be determined by estimating the hemoglobin only, for there are other oxygen carriers — oxidases, peroxidase and catalase. Catalase is an enzyme which has the power of decomposing hydrogen peroxide, but this is about all that is known concerning its function. The power of the blood to split hydrogen peroxide is influenced by the number of red corpuscles, the thyroid gland, the renal function and the action of salts, acids and alkalies. The catalytic activity of the blood of a series of normal individuals varies, but that of a single normal individual is constant over long periods of time. The catalytic activity of the blood in disease is of diagnostic value in typhoid fever, lobar pneumonia, acute peritonitis, uremia, malignant disease and disease of the thyroid gland.

9. Mills and Congdon report a series of experiments on cats in which they studied the absorption of injected oils from the subcutaneous spaces. The ultimate object of this work was the application of fat injections in wasting diseases, especially tuberculosis, in which intolerance to fats is universal. They find that olive, peanut, cocoanut, sesame, cottonseed, lard oils, unsalted butter fat and lard may be given hypodermically over a considerable period without local irritation. Oils and fats given subcutaneously are absorbed by means of the lymphatic system and eventually reach the thoracic duct. Lymphatic vessels and glands in contact with and transmitting oil for any length of time become hypertrophied and better able to carry oil. Emulsified oils and fats injected during starvation are absorbed in amounts sufficient to furnish from one half to two thirds of the full calorific requirement of the animals injected. The injection of oils subjected to lipolysis causes death, which is due apparently to the production of oleic or other acids with the possible formation of toxic quantities of soaps. Oil absorbed from the tissues after

subcutaneous injection is (*a*) burned in the body for the production of heat and energy, thus sparing the body fat; (*b*) retained as such within the organism; or (*c*) possibly converted into body fat by reconstruction in the liver. [L. D. C.]

1. Coley uses the word "cancer" to include all forms of malignant tumors, both of epithelial and connective-tissue origin. In a paper in 1897 he reported 170 cases of sarcoma, 46 of which had histories of antecedent trauma. To this series he now adds 800 cases of sarcoma, 179 of which have histories of antecendent trauma. Synopses of the previously published 46 cases and the present 179 cases are presented showing the age, sex, type of sarcoma, site of tumor, nature of injury and interval between injury and appearance of tumor. Of these 225 cases the tumor developed within one month after injury in 117, within six months in 171. Tumors originated in bone in 105 cases, in soft parts in 120. Synopses of 52 cases of carcinoma of the breast associated with antecedent trauma are then given. In 19 of these the tumor appeared within a month after injury, in 30 within six months after injury. The histories of several cases are given in detail. Even the most incredulous must admit some of these cases are most suggestive of acute traumatic malignancy. Case 1 is in brief as follows: Man, thirty-five, spiral fracture at junction of middle and upper thirds of left humerus; x-ray shows fracture without trace of new growth, severe pain at site of fracture in few weeks; second x-ray shows well-marked tumor involving both central portion of bone and periosteum; tumor rapidly grew; five months after injury operation by Dr. Finney, of Baltimore, who, thinking amputation offered no hope of cure, did a curettement of central portion of tumor; Dr. Bloodgood reported spindle-celled sarcoma, mixed toxins given by Coley; condition improved with toxins and several curettements; Dr. Ewing reported spindle-celled sarcoma; shoulder-joint amputation one year after injury by Coley (January, 1911); patient at present well.

2. Whitman, in an article well illustrated with diagrams, photographs and x-rays, again explains the principles of his treatment of fractures of the neck of the femur by the abduction method. The procedure of application of these principles is given in great detail. The most important manipulation in the after-treatment is to draw the limb out to the position of abduction several times a day as soon as the plaster is removed. This manipulation is continued until the patient regains ability to place the limb in the desired attitude. If this be neglected, the limb assumes the attitude of adduction and flexion, a natural adaptation to weakness and discomfort. In youthful subjects in whom there is no question of the inherent capacity of the tissues for repair, end-results with deformity, disability and non-union following old routine treatment argue against the efficacy of this treatment. Whitman and others have obtained better results with his abduction method in this class of subjects. He now, therefore, advocates for the first time its application to elderly subjects. In this class the question of the inherent capacity of the tissues for repair arises and, therefore, the abduction treatment "must be considered as an experiment, to be continued or abandoned according to the indications." Owing to the danger of hypostatic pneumonia in elderly subjects, Whitman recommends the elevation of the head of the bed. This posture has the additional advantage of congesting the limb which should favor repair. Whitman has applied his method in the case of a woman of seventy-three, the mother of a physician, with excellent result (no deformity or shortening and practically no limitation of motion).

3. In speaking of fractures of the shaft of the femur in which carefully prepared x-ray plates (taken from several viewpoints) show much displacement of the fragments, Harte says, "I feel confident that there is no positive or definite line of treatment open to us except the exposure of the fragments of the bone by formal dissection and the restoration of the fragments, actually seeing the parts perfectly dovetailed back into their original position, which is positive assurance against rotary displacement and the first step toward procuring good alignment." He prefers an incision on the outer side of the quadratus femoris on the anterior surface of the thigh to one on the outer side of the leg between the line of the flexor and extensor groups of muscles. He recommends the Martin method of extension to approximate the ends of the bone for plating. All through the process of convalescence suitably applied splints and extension should be maintained to obviate the tendency to displacement.

4. Alexander analyzes 56 cases of fracture of the patella, with reference to sex, age, nature of accident, type of fracture, infection in early and late operations, and merits of absorbable and non-absorbable suture material. The only reason for not operating immediately after injury lies in the realization that our technic is not always perfect. Infection is less likely to occur six to ten days after injury. The author strongly advocates the actual suture of the bone fragments rather than approximation by suture of the fibrous expansions of the quadriceps tendon and urges the use of silver wire for this purpose. [T. W. H.]

THE LANCET.

MAY 6, 1911.

1. *HERTZ, A. F. *Goulstonian Lectures on the Sensibility of the Alimentary Canal in Health and Disease. Lecture III.*
2. *MAYLARD, A. E. *An Address on the Symptomatic Vagaries of Partial Pyloric Obstruction.*
3. DUCKWORTH, D. *A Lecture on Some Indications of Inborn Proclivity to Gout.*
4. *WILSON, T. *On the Suprapubic Transverse Fascial Incision in Gynecology.*
5. SARGENT, P. *Aneurysm of the Innominate Artery; Proximal Ligature; Recovery.*
6. MORISON, A. *On Reversible Pulmonary Crepitation in Cardiac Failure.*
7. HEILBORN, W. E. *Infant Mortality.*

1. Hertz, in the third of the Goulstonian Lectures, discusses esophageal pain, gastric pain and intestinal pain and variations in the sensibility of the alimentary tract. He sums up the three lectures and presents his conclusions in detail.

2. Maylard discusses the various symptoms of partial pyloric obstruction and their wide diversity in different instances. The points of most significance he considers to be intermittent attacks of dyspepsia coupled at times with the physical signs of gastric peristalsis or gastrectasis in often otherwise healthy patients.

4. Wilson believes that the transverse fascial incision presents many advantages over the usual longitudinal incision in gynecological operations in that there is much less risk of ventral hernia following, there is more room to work in and the appearance of the scar is more pleasing. [J. B. H.]

DEUTSCHE MEDIZINISCHE WOCHENSCHRIFT. No. 17.

2. Hecker and Otto report in detail their studies on the disease named after Weil. This disease has occurred chiefly among soldiers and is characterized by sudden onset of general aching in head, shoulders and spine, high fever, relatively slow pulse, vomiting, constipation, albumen in the urine and enlarged liver. As a result of their studies they conclude as follows: Weil's disease occurs almost exclusively in the hot seasons of the year. It is an infectious but non-contagious disease. The course of the illness is a characteristic one but during epidemics quite atypical cases occur. At the height of the epidemic the most severe types occur in people who have worked or swum strenuously. As yet no causative agent has been found. No bacteria have been cultivated and they think it is due to a micro-organism which is carried possibly by an intermediate host. [C. F., JR.]

4. The author mentions two varieties of tubercular meningitis: First, the severe type where the diagnosis lies between typhoid, sepsis, miliary tuberculosis and a central pneumonia. Second, early tubercular meningitis, where the diagnosis of meningitis can be made, but it is difficult to determine the exact cause of the infection. He points out the extreme difficulty of finding the tubercle bacillus in the spinal fluid, and then offers an aid in differential diagnosis.

First, In tubercular meningitis there is a clear cerebrospinal fluid, with a lymphocytosis, either alone or accompanied by polynuclear leucocytes, the latter showing marked degenerative changes especially in the nucleus, in contradistinction to their appearance in the epidemic form.

Second, A heavy sediment, and a small amount of albumin in the spinal fluid denote some other organism than the tubercle bacillus. A small sediment and a large amount of albumin, on the other hand, denote a tuberculous infection.

A report of a number of cases, with the findings in the spinal fluid in each case, follows. [J. B. S., JR.]

## Obituaries.

### EMMA W. MOOERS, M.D.

Dr. Emma W. Mooers, custodian of the Neuropathological Collection at the Harvard Medical School, died May 31, at the age of fifty-two. The immediate cause of her death was a streptococcus meningitis, secondary to an infection of the hand and subsequent septicemia.

Dr. Mooers was born in Greendale, Wis., and received her degree in medicine at the University of Michigan in 1884. She thereafter for ten years devoted herself to the practice of general medicine, in which she was eminently successful. The greater part of this period was spent in Arlington, near Boston. In 1896 she began a serious study of neuropathology, under the direction of Dr. E. W. Taylor, at the Harvard Medical School. She at once showed a peculiar capacity for the work, combined with an admirable enthusiasm, which led, after completing her preliminary studies, to the offer of positions of responsibility. She filled successfully laboratory positions in several state institutions, and in the fall of 1900 went abroad and worked in the laboratory of the Claybury Asylum near London. On returning to this country, she accepted a position at the McLean Hospital, where, associated with Dr. August Hoch, she continued to prosecute her work, particularly in the line of neuropathological technic. The fall and winter of 1903–1904 she spent with Benda in Berlin, and the following summer continued her work with Weigert at Frankfort, where she remained until after her distinguished teacher's death; she then went to Munich and studied under Kraepelin, and soon became a valued assistant in the laboratory. She was there particularly associated with Alsheimer in his important and far-reaching investigations. Her knowledge not only of her subject, but of French and German as well, made her an invaluable aid in the teaching of foreign students, and she soon made a place of importance for herself in this laboratory. During the latter years of her stay in Germany she perfected herself in the elaborate technic of the Wassermann reaction and finally returned to this country about two years ago expert in this work as well as in the broad field of neuropathology. Soon after her return she began work at the Harvard Medical School and there became associated with Prof. E. E. Southard. At the time of her death she was actively engaged in general neuropathological work and especially in the development of a laboratory for Wassermann technic. She had also very recently been appointed custodian of the Neuropathological Collection, and in general seemed finally to have obtained the position for which she had long and conscientiously prepared herself, and for which she was well fitted, both by temperament and training. Shortly before her death she had completed a piece of original work on the condition of the peripheral nerves in experimental poliomyelitis which is likely to prove a positive addition to the subject, showing, as it does, the probability of a true neuritis as a result of the infection. She was also much interested in the histology of so-called Landry's paralysis; it is to be hoped that her investigations in this field may receive posthumous publication.

Her death is not only a distinct loss to this community but also to the cause of scientific medicine in general. As a technician she was adept and thorough; in carrying out the Wassermann reaction her devotion to detail left small chance of error. It is not to be questioned that in this latter work she was one of the best prepared and most skilled students in this country. Her enthusiasm and her methods of work were admirable. It is perhaps invidious to speak of German standards, but, at the same time, one cannot deny that ideals of thoroughness have attained a higher place in that country than in this. However this may be, Dr. Mooers believed thoroughly in German methods and did not allow herself to swerve in the least from this allegiance. To know her work was to have confidence in it. For all these reasons, quite apart from her personal qualities, her death will be mourned by a wide circle both of those who knew her personally and of those who knew her only through what she had accomplished.

### HENRY CLAY ANGELL, M.D.

Dr. Henry Clay Angell, who died last week in Boston, was born at Providence, R. I., in 1829. He received the degree of M.D. in 1853 from the Hahnemann Medical College of Philadelphia, and subsequently studied for a time in Europe. On his return he settled at Lynn, Mass., and practiced his profession there for three years. He then went abroad again to study ophthalmology, and since his return had lived in Boston. He was author of a textbook on diseases of the eye, and for twenty years was professor of ophthalmology at the Boston University Medical School. He was a member of the Massachusetts Homœopathic Medical Society and of the American Institute of Homeopathy.

Dr. Angell had a strong taste for music and painting, and was himself an artist and critic of considerable ability. In an obituary notice of him in the daily press, Mr. Arlo Bates has said: "Behind the connoisseur, however, was the man who was better than all: a man of admirable sanity, of shrewd insight, of wide range, of sweet sympathies, of subtle humor, of humanity the most winning. We who knew and loved him can only feel that the memory of such a friend is more vital and lasting than companionship with the many."

## Miscellany.

### BEQUESTS TO HOSPITALS.

The will of the late Mrs. Darius Wilson, who died at Cambridge, Mass., last week, has been filed for probate at the East Cambridge court. It contains a large number of charitable bequests, among which is one of $10,000 to the Ohio Hos-

pital for Women and Children, Cincinnati. The sum of $5,000 each is left to the Children's Hospital of Boston and to the Boston Floating Hospital; $2,000 each to the Boston Nursery for Blind Babies and the New England Peabody Home for Crippled Children. It is further provided that on the death of one of the personal legatees of the will, the residue of the principal of a fund left in trust for his benefit shall be divided equally between a dozen charitable institutions, each of which will probably receive from this source about $2,500. Among the beneficiaries under this provision are the Children's Hospital of Boston, the Boston Floating Hospital, the Massachusetts Homœopathic Hospital, the New England Peabody Home for Crippled Children, and the Convalescent Home of the Children's Hospital, Wellesley Hills.

The will of the late Ann Lee, of Boston, who died on May 28, has been filed for probate. It contains a bequest of $200 to St. Elizabeth's Hospital.

## PREVALENCE OF SMALLPOX IN THE UNITED STATES.

THE weekly report of the United States Public Health and Marine-Hospital Service for June 2 presents a statement of the "prevalence and geographic distribution of smallpox in the United States during the calendar year 1909." The total number of cases reported was 24,099, with 150 deaths, but in many states the report is only partial, and some made no report at all. Complete reports from twenty-seven states, with an estimated population of 58,839,200, show a total of 19,534 cases, with 92 deaths. These figures are lower than those of the preceding year, but are regarded as "excessive when compared with those reported in other countries, and regrettable when the preventability of the disease is considered." The distribution of the disease is illustrated by graphic maps. Its prevalence appears to have been greatest in Kansas, Illinois, Utah, North Carolina and Oklahoma. Its ratio to population was by far the greatest in Utah.

## INTERSTATE CARE OF LEPERS.

IN the issue of the JOURNAL for June 1 we noted the request made by the governor of Rhode Island for special legislation by Massachusetts to permit the admission to Penikese Island of the leper recently discovered at Pawtucket, R. I. A similar request has now been made by the governor of Connecticut in behalf of a Russian leper recently found in Hartford, Conn. There seems no immediate reason why one state, having a leper colony, should not receive and care for inmates from other states not so provided. Such action would seem to be in the interests of economy, humanity and public safety. Probably the special legislation necessary to make it legal will be introduced for consideration before the General Court of Massachusetts.

## RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, MAY 20, 1911.

## SOCIETY NOTICES.

MAINE MEDICAL ASSOCIATION. — The fifty-ninth annual meeting will be held at the City Hall, Augusta, Me., Wednesday and Thursday, June 28 and 29, 1911.

MASSACHUSETTS MEDICO-LEGAL SOCIETY. — The annual meeting will be held at Harvard Medical School, Building A (Administration Building), Room 205, on Tuesday, June 13, 1911, at two o'clock. The annual lunch will be served at 1.30 in Room 110 of Building A. Annual reports and election of officers. The following papers will be read and discussed: 1. "Points of Medico-Legal Interest in the Glover Murder Case," George L. West, M.D., Medical Examiner, of Newton. 2. "The Murder of Frank Cusumano," John A. Peterson, M.D., Medical Examiner, of Hingham; Prof. Wm. F. Whitney, Harvard Medical School; George Burgess Magrath, M.D., Medical Examiner, of Boston.

OLIVER H. HOWE, M.D., *Recording Secretary.*

## RECENT DEATHS.

EMMA WILSON MOORES, M.D., M.M.S.S., died at Boston, May 31, 1911, aged fifty-two years.

DR. OLIVER H. ARNOLD, of Providence, R. I., died in that city last week. He received the degree of A.B. from Brown in 1865, and that of M.D. from Harvard in 1867. After practicing his profession for a few years in Pawtucket, R. I., he studied medicine abroad for a time, and on his return settled at Providence. He was associated with the department of biology and comparative anatomy at Brown University, and was a member of the American Institute of Homeopathy.

DR. CHARLES H. MAGOON, who died last week at Wakefield, Mass., was born in 1840. He was a pioneer settler of Algona, Ia., where he spent his early life raising fruit-trees. In 1865 he returned to Massachusetts, studied dentistry, and had practiced his profession ever since, chiefly at Wakefield. He is survived by his widow.

DR. FRANCIS JOSEPH WELLER, who died last week at South Boston, was born in 1862. He received the degree of A.B. from Boston College in 1888, and that of M.D. from Harvard in 1894. He was an assistant in otology at the Tufts Medical School and at the Carney Hospital. He is survived by his widow and by two children.

## Original Articles.

# OBSTETRICS IN GENERAL PRACTICE.*

BY A. WORCESTER, A.M., M.D., WALTHAM, MASS.

Some years ago I reported to this society three series of two hundred midwifery cases.[1] As a basis for this paper I now report five hundred additional cases, occurring in my practice between Aug. 8, 1894, and March 12, 1909. I shall not venture to tabulate the dry statistics of the duration of the different stages of labor or of the fetal presentations and positions, as I did with my first six hundred cases. Any yet, without more than passing reference to the normal cases, using them merely as a background for the description of what is abnormal, no idea could be given of the ordinary midwifery practice of a general practitioner.

In my clinical records I have made note of every deviation from the normal, and of all unusual occurrences. But what, we may well ask, is the normal? If the woman delivers herself, without any interference by physician, nurse or neighbor, and without any harm to herself or her child, then of course the case can be classed as normal, or at least as *accouchement au naturel*. Here is an illustration: Mrs. M., age thirty-three, according to her own story, began her tenth labor with three hard pains. She went downstairs and had four more pains, when the waters broke; then she went upstairs and had four more and found baby and placenta on the floor. Before I arrived she had tied and cut the cord. There seemed little left for me to do.

But unless the woman in labor takes to the woods, as in fact one of my patients did, she can seldom escape having her labor assisted; and such assistance is more or less an interference. Take the management of the third stage of labor, for instance. The old practice was to leave the placenta to come when it pleased. After several days of waiting, if, as occasionally happened, it showed no signs of coming, then, perhaps, something was done about it. I remember such an instance in the practice of an excellent physician of the old school. Laugh as we may at such conservative reluctance to interfere with Dame Nature, we can but admit that in the customary hurrying of the third stage by Crédé's method, which, by the way, is much to our own convenience in letting us get away, our patients occasionally do lose more blood than they should. What danger is there, then, in non-interference? None, I believe, and I wish I were able to back up my belief with more than a very few of my cases where the patient delivered herself of the placenta. In none of these cases, however, was there any trouble. The woman already referred to, who, when in labor, took to the woods, the next day walked a mile back into town, carrying her baby in arms, and was not delivered of the placenta until she had been put to bed eighteen hours after the birth of the child. There was not the least drawback in her recovery. Nor was there in an earlier case where the illegitimate mother hid her dead baby, and the next day journeyed to another state. Two days afterwards I found her in the police station, after a hundred miles of traveling, with the placenta still undelivered.

It is not my object, however, to decry the Crédé method of hastening the third stage of labor just because it is of such convenience to all concerned, but I want to point out that it is a distinct interference with nature and, therefore, should be subjected to most critical scrutiny. In my previous reports it seemed likely that the cause of the unusually large percentage of post-partum hemorrhages which occurred in my early practice lay in hurrying the delivery of the placenta. And this likelihood was increased by my being able afterwards to report a smaller percentage of hemorrhages and a correspondingly longer average duration of the third stage. But now, on the other hand, in this series the average duration of the third stage (nineteen minutes) is no longer, and yet the occurrence of post-partum hemorrhages has again decreased from 6% in my best previous report to 2% in this series. Setting aside the cases of placenta previa, there were only ten cases where as much as a quart of blood was lost. In four of these the hemorrhage followed instrumental delivery under anesthesia. In the remaining six cases the duration of the third stage was thirty minutes in one, fifteen minutes in three, ten minutes in one, and in one not noted. Happily no serious consequences followed beyond a retarded convalescence.

I believe that my better showing in this respect is due to having taken care that the uterus should be firmly held, for a longer time than I formerly thought necessary, before "fixing up." One hour of absolute rest after the baby's birth, or at least one-half hour after the delivery of the placenta, is none too much of a precaution. The only other change in my procedure has been the discontinuance of ergot, in which I have lost all faith. When not needed, it undoubtedly provokes uterine contractions; when needed, it is, in my opinion, worthless.

This discussion of the third stage may seem to be beginning the study of my cases at the wrong end, but it allows a sharper definition of my use of the word "normal." Except for this acknowledged interference with nature in the third stage of labor, 54% of my cases are definitely recorded as normal, and in 16% more I have recorded nothing to the contrary.

Although in these 350 cases I have found no unusual occurrences in either the labor or convalescence, I am not yet ready to dismiss them from consideration. For I am persuaded that excellence in the art of midwifery, even if not in obstetric science, still depends very largely upon the management of the normal case. And I confess to some disquietude of mind over the practices advocated now-a-days by the progressives, if I may so designate our brilliant obstetric specialists. But what is more presumptuous than for a general practitioner to

* Read before the Obstetrical Society of Boston, March 28, 1911.

[1] *Vide* Boston Med. and Surg. Jour., vol. cxi, p. 427; vol. cxiv, p. 28; vol. cxxxv, p. 355.

criticise the specialist! It is nothing less than a complete reversal of their respective functions. Nevertheless, in reporting one's work, even if there seems to be some defiance of modern canons, it is necessary to describe one's methods.

To begin, then, with my confessions: in my visits to pregnant patients, even if primiparæ, I have not invariably measured their pelves, their intra-uterine progeny or their husbands. Of course I have collected such data, or some of it, where there was exceptional reason, and also I am ashamed to say, where there was no reason, beyond the supposed necessity, in the patient's mind, for so doing. Fashions are infectious.

In the immediate preparation for the labor of my patients, I have so often been forced to strictest economy that I have become accustomed to doing without, and, indeed, to considering superfluous, much that I find some families acting under other advice, have provided. I have taken comfort in recognizing that after all the bringing forth new life into the world, instead of being a sickness or a cataclasm, is nature's most natural process, and that the very most I can do at such times is to help and not hinder. I have, therefore, tried to simplify rather than complicate the family enlargement problem. To this end I have given much time and strength to the training of nurses for this special service. And I have found that nurses properly taught are of immense help at such times to the physicians, the family and the patient. But I protest against some of the fads I find nurses being taught now-a-days. For instance, it is abominable to shave the patient before or during her labor, as if for a serious surgical operation. I must not, however, while describing my own methods, criticise others. And yet I want to emphasize the advantage the family physician has over the specialist in his obstetric practice, in keeping childbearing in true perspective, in maintaining its ordinary matter-of-course character. Of utmost importance is it to ward off from the expectant mother all anxiety and foreboding. Let me not be misunderstood. My own list of disasters is too long for me to ignore the dangers incident to childbearing, or to counsel the accoucheur even to forget their immanence. But these fears should never, directly or indirectly, reach the patient. And the excessive precautions and the extensive preparations now fashionable most certainly do tend to frighten pregnant women and to deter them from subsequent childbearing.

The management of the first stage of labor I have almost always entrusted to the nurse. In no other way would even a moderate obstetric practice be possible for the general practitioner. And, fortunately for him, such service can be performed by the nurse better than by any man. Not only the cleansing enema can be better given by the nurse, but also the needed cheer and comfort and reassurance. True, the physician who relies upon either his own guesswork or upon his nurse's judgment as to the probable hour of the delivery will sometimes miss being on hand. But where the child comes into the world expeditiously, a properly trained nurse can manage the delivery well enough and also give first aid in emergencies. At any rate, in my practice I have found no harm resulting from leaving the care of the first stage to the nurse. Where the babies have been born before my arrival there may have been a slightly larger percentage of perineums to repair, but probably not larger than in cases of similar precipitancy where I was in immediate charge.

When I remember how much I have tried to do for my patients in the second stage of their labors, I am again compelled to apologize for my use of the term "normal" in reporting these 350 cases where nothing unusual happened. The fact is I have been constantly trying to learn how to give most help. In the matter of posture, for instance, I have urged my patients to take what ever posture they wanted. So some have been delivered while lying on their sides, or backs, and some while on their hands and knees, and some while sitting on the edge of the bed, as is the custom among the Appalachians. When no progress is being made, I have found it a good plan to urge radical change of posture.

With few exceptions I have given an anesthetic to dull the suffering from second-stage pains. For this purpose ether is contra-indicated, except in Boston. Chloroform is much better, but not so serviceable as a mixture of it with ethyl bromide. But I need not repeat my opinions upon this particular.[1]

In trying to help on the progress of the delivery I have, of course, often dilated the cervix, flexed the baby's head and rotated it into more favorable position. I do not know how much physical help has thus been given, but I am sure that many women have been very grateful for these efforts, and also for the hot fomentations I always apply to the stretched perineum, thereby, I am sure, increasing its elasticity. But I have never found a patient appreciative of my holding back her baby's head in order to secure safer dilatation of the ostium vaginæ. It is just then that an anesthetic is of greatest service, in thus allowing the delivery of the head between pains. I am satisfied that such is the easiest way for the mother as well as the safest for her perineum. So much for my normal cases.

Of the remaining 150 cases, many have been kept out of the normal class for trivial causes. For instance, in 57 of these cases there is record of perineal laceration; but in 51 the laceration at most did not extend more than halfway to the rectum, and in some cases only a single catgut suture was required. In 2 cases the tear reached the anal sphincters and in 4 cases went through them: these were hard forceps cases. In 5 cases twins were born. This, to be sure, ought not to be considered abnormal, but it relieves the monotony of ordinary midwifery work, and sometimes demands much of the accoucheur. I shall refer to one of these cases later.

In 3 of these cases, one of the twins presented as a footling. And of the single pregnancies, in

[1] *Vide* BOSTON MED. AND SURG. JOUR., Aug. 26, 1897.

one case the hand presented, in 3 a foot, and in 5 the breech. In 5 other cases podalic version was performed. So I have in all 17 babies to account for who came into the world feet first. Four of these were stillborn, and one, an eight-months' fetus, died the following day. One of the four was a two-pound premature baby, one had no pulsation in the cord when I first examined, but 2 died because of the difficult delivery.

I dread breech deliveries more than I used to, and so I find myself employing axis traction forceps, where formerly I should have done podalic version, especially in cases of occiput posterior.

In 33 of my 500 cases the fetus was in this unfavorable position, O. R. P. in 30 and O. L. P. in 3. In only 8 of these was the labor terminated without assistance. In one, where the cord prolapsed, I delivered by podalic version. In 21, after rotating the occiput forwards, I delivered with forceps. Once I brought the head down to the vulva with the occiput posterior, and then rotated it forwards and reapplied the instruments. Once I pulled the head through face under the pubic arch, and once the baby was thus delivered by the unaided mother. Three of these occiput posterior babies were stillborn; in one the cord was not pulsating when I first examined, but forceps delivery had been previously attempted by the physician attending; in the second, though after delivery the heart beat feebly for a few minutes, the epidermis rubbed off easily and there was much meconium in the liquor amnii from the first escape of it; the third died from the delivery, apparently from strangling by the cord around its neck.

With such experience it is natural that I should consider a posterior position of the occiput as a really serious complication of labor. And in view of the almost certain prolongation of the woman's suffering, and of the great probability of her having to be operated upon eventually, I believe it best to rotate the occiput forwards while the head is above the brim, and then, if it does not so engage, I believe high forceps should be applied, and, of course, axis traction.

Besides these 21 cases just mentioned, I delivered 32 others with the forceps. Only one baby was stillborn. There had been no motion felt for two days, as I afterwards learned, but it is not unfair to assume that the child died during its exceedingly difficult delivery. Here are my notes of the case:

Mrs. B., thirty-three years old, a very stout but muscular woman, had been in labor, with at most hour intervals, for three days. I had delivered her safely twice before. After tremendous pains she brought the head to the inferior straits, in O.L.A. position, but could do no more. With forceps, which slipped off several times, I finally succeeded in delivering the head. I had even more difficulty with the shoulders, and broke one arm. The girl baby, stillborn, weighed 10½ lb. The next year I delivered her safely. But I suppose in the management of this case I am liable to the charge that I should have known the baby was too big for any delivery except by Cæsarean section. However this may be decided, it is the only one of my 500 cases where, even in the light of results, I think I ought to have elected that operation *at the time when I was first called in*. Sometimes I have wished that I had been called in earlier, as, for instance, in the case of Mrs. H., a stout, muscular woman of forty years, whom I first saw when she had been in labor for four days. She said she had been delivered twelve years before of a dead child. Her pelvis measured between the iliac crests 8½ inches, anterior superior spines 7 inches, trochanters 11½ inches, and the external conjugate 6½ inches; evidently a justo-minor pelvis. No fetal motion had been detected for two days. The os uteri was half dilated and easily distensible; the liquor amnii had all escaped; the head presented, very boggy. On passing my hand into the uterus, the very large fetus was found to be dead. Podalic version was easily done, but so small was the pelvis and so large was the child that, after one leg was delivered, it was only with greatest difficulty that the other leg was brought down. After an hour the hips, and, after still another hour of tremendous tugging, the shoulders were delivered. During these efforts the cervical vertebræ were dislocated. Of course this fetus should have been dismembered, but my instruments for this operation were twenty miles away. When I got them the head was delivered after craniotomy.

The chances of successful issue from a second pregnancy are, of course, largely dependent upon the results of the first. Where the first child is lost, in spite of all operative attempts to save it, a second pregnancy of course occasions serious misgiving. I am afraid that physicians, after failing to deliver a living child, too often have been at fault in warning such families against future pregnancies. This is ignoring the better chances in second pregnancies, as well as all possible expedients.

In September, 1902, when called in consultation, I twice failed to deliver a primipara of a living child, and in both cases in their second pregnancies I succeeded. Here are my notes:

Mrs. C., thirty-seven years old, stout and muscular, had been in labor twelve hours. The pains had slackened; the head presented O.R.P.; the cervix was only partially dilated; the cord found to be pulsating slowly and feebly. I at once dilated the cervix, performed podalic version and with great difficulty succeeded in delivering a large stillborn child. In applying forceps to the after-coming head, I made the mistake of inserting beneath instead of above the child's body, and so lost time. But I have never seen a breech-delivered child live after such hauling as was necessary. After the mother's recovery, I found on careful measurement no reason why she should not be safely delivered. The impediment in the first instance was the unyielding inelastic soft parts, not the pelvic size or shape. Fifteen months later I had the joy of delivering her safely.

The second of these patients, Mrs. R., thirty years old, had been in the second stage of labor for several hours when I was called in. Forceps had been tried in vain. I found the head presenting in O.R.P., the cord not pulsating. After rotating the occiput forwards I succeeded, after very hard pulling, in delivering a 10-lb. dead boy. Her pelvic measurements were not out of the way, and I willingly agreed to help again if needed. That time, at the end of twenty-four hours her pains had become good for nothing, the position was favorable, and my axis traction forceps (or rather Dr. Friedman's, which I value exceedingly) went on

easily, and after hard pulling I delivered a 7-lb. girl. Both times the perineum was torn through the sphincter ani.

In deference to the present fashion of delivering by abdominal section, some apology is perhaps due in reporting even successful cases of delivery *per vias naturales*, where the conditions would have warranted more up-to-date methods. But when one is off many miles from his base of supplies and from his colleagues, he naturally hesitates in explaining to the family the inestimable advantages of a Cæsarean.

Here is a case where perhaps I need not have come so near breaking my own back.

Mrs. K. admitted twenty-nine years. She had had a miscarriage in the shady past. After eighteen hours of labor the os uteri admitted only two fingers. Pains were almost continuous. Under anesthesia I dilated the cervix. And then after three hours and no engagement of the head, I applied forceps and with great difficulty delivered a 10-lb. boy without lacerating the perineum. But the mother suffered excruciating pain in the left hip and pubic arch for a long time afterwards, and also from incontinence of urine. She would probably have made a better recovery had she been delivered by more modern methods.

In spite of the opposition of the specialists to the premature induction of labor, where the pelvis does not allow the passage of a full-term child, nevertheless it is an operation that will continue to be done by general practitioners. Here, for illustration of its usefulness, are the notes of three successful deliveries of Mrs. C. by this method. She was thirty-three years old, and in childhood had suffered from hip disease, resulting in complete ankylosis of the left hip joint. Her pelvic measurements were, between iliac spines 8 inches, crests 9 inches, tuberosities 3 inches, trochanters 10 inches, external conjugate 7 inches, internal diagonal conjugate 5 inches. Five weeks before the date of her expected confinement she was admitted to the Waltham Hospital, where labor was induced by the insertion of bougies and then Barnes' dilators. After several hours of ineffectual labor, the cervix was dilated manually and the child, a 5-lb. girl, delivered with, I must acknowledge, considerable difficulty, but both mother and child did well. Exactly one year afterwards the same operation was repeated, with the same happy results, the only complication this time being the bad laceration of the cervix which required immediate repair. Four years afterwards Mrs. C. came to the hospital for the third time, and again after the same treatment she left with a girl baby. She and her three vigorous daughters have thriven ever since.

Peculiarly ungracious must it seem to report a case where the woman, already on the operating table, under full anesthesia, ready for the knife, was delivered in the old-fashioned way. But here are my notes: Mrs. J., thirty-one years old, had borne three living children. After the third she was operated upon in the Boston Homœopathic Hospital for repair of perineum and cervix and for ventral suspension of the uterus. These operations were done all right, for in her next pregnancy when again in labor her family physician could not find the os uteri, nor could a consultant summoned for the purpose. So she was brought ten miles to the Waltham Hospital for Cæsarean section. She had been having indefinite labor pains for ten days. With great difficulty I succeeded in entering the vagina with my whole hand, and then in finding the half-dilated os uteri further up and further back than would be believed possible. The child lay crosswise, its back anterior and its head to the left. I succeeded in doing podalic version and in delivering the child, a poorly developed boy who died a week after.

Eclampsia appeared or threatened in ten of my cases. In four there was a spontaneous miscarriage; in one, an epileptic, after a severe convulsion, a dead premature fetus was born; in one the threatened convulsions were averted and after a normal labor a 5-lb. girl was born; in two, after manual dilatation and delivery by podalic version, the premature child was lost; in two by the same method two were delivered alive. All the mothers did well. Here are my notes of two of these cases:

Mrs. B., twenty-six years, had gone through her previous pregnancy all right. This time, six weeks before she began her labor, noticed dimness and blurring of vision, her feet and legs were swollen, and her urine was scanty. She could not read and once had headache. She was treated vigorously with diuretics, and as the amount of urine increased the edema left her. Her labor was normal and her recovery uneventful.

Mrs. E., thirty-four years old, began her first labor at midnight March 1. In the early morning of March 3 the cervix was fully dilated but the head was not engaged after several hours of hard labor. She had been passing urine freely, and it was free of albumin on Jan. 1 and Feb. 1. Suddenly she suffered a severe convulsion. The only warning we had she gave to her mother, shortly before, telling her she saw stars. I at once delivered her, with high forceps, of a 9¼-lb. boy. She had no further trouble.

There were three cases of placenta previa. The three babies lived, but, alas, two of the mothers died and both left large families. I ought perhaps to include a fourth similar disaster, where, although I did not myself operate, I stood by advising a younger colleague. But if I should do that, I ought in fairness also to include a fifth case where I stood by giving advice where the mother was saved. As I am determined to be my own severest critic I report in detail my mistakes and failures, without excuses.

Mrs. N. consulted me in May, 1898, because she had been flowing, although only eight months pregnant, and because she had heard the week before of the death of a neighbor from placenta previa. She knew I had assisted in the delivery of that woman and that I had blamed her family for not having notified their physician of her previous hemorrhages. For Mrs. N., I made all possible arrangements. At a meeting of this society I anxiously asked advice. The only new suggestion then was to ligature the uterine arteries if nothing else would stop the hemorrhage. When my patient sent for me in June, she was flowing slightly and her labor had begun. The placenta was central, and as the labor advanced there was considerable hemorrhage. With all the advantage of an operating table, able assistants and every possible provision in the way of instruments and materials, I dug through the placenta, did podalic version, delivered a living child, and then saw the mother bleed to death in spite of everything I could do. The uterus never showed the least sign of contracting. Packing it was useless. And my deep sutures were tied round the uterine arteries too late.

In this case, of course, for the mother's sake I should have endangered the child by waiting for its natural delivery after the version. That is all very well in theory, but, after the placenta is dug through, and, of course, almost entirely detached, not to draw the child out of danger requires more nerve than I possess. If exactly impartial regard had been given to both lives, then the delivery would have been by Cæsarean section, which alone allows perfect control of the uterine arteries and may so prevent their awful outpour.

In my next case, in spite of my determination never again to employ the same methods, I did just that. But I was caught unawares. Mrs. W., thirty-eight, I had delivered three times previously. Until an hour before I was summoned she had not lost a drop of blood, but in that hour she had lost a lot. I found the vagina full of clots, the os uteri half open, the pains coming fast. I did not dare withdraw my hand, so much blood followed my first examination, but, instead, while hunting in vain for some lateral chance, I detached the placenta. There was then nothing to do except deliver it, and get out the child, which fortunately presented by the breech. I packed the uterus with towels soaked in hot 2% acetic acid. I dragged out the cervix, which was lacerated up to the vault, and stopped the spurting arteries with tendon sutures. About three pints of blood was lost during the operation, and I judged about as much before. Except for the sutures in the cervix I do not believe the mother would have lived to care for her 8-lb. daughter.

My third case was Mrs. W., thirty-nine years old, in her fifth pregnancy. I had delivered her in her first with high forceps, of a 9-lb. girl; in her second in the same way of a 10¼-lb. boy; in her third, also with instruments, of a daughter; and in her fourth confinement, of twin boys. I nearly lost her then. She was eight months pregnant, very sick with the grippe, suffering from headache and uremia and almost constant uterine contractions; her condition seemed so alarming that I decided to deliver her. I dilated the cervix, and finding a fair-sized head presenting O. L. A., I applied forceps but could not deliver it. On further examination I found a twin's head locked under the first fellow's chin. After pushing him back, the first was easily delivered, a boy of 7¼ lb. There was considerable hemorrhage, and, after the second boy, also of 7¼ lb., was delivered with forceps, face under the pubic arch, the hemorrhage was alarming. We could not get hot water because the father of the child had collapsed in the bathroom, where he lay on the floor vomiting and purging. At one time it seemed to both nurse and physician unlikely we might save even the old man. But all pulled through. And now to return to my notes of the poor woman's fifth pregnancy, two and a half years afterwards, during which, as I afterwards learned, she had had many slight hemorrhages. On the seventeenth of June, 1907, she was taken to the Waltham Hospital, having had a serious hemorrhage the day before. She was very anemic. June 20 her labor began. The pains were severe that night and there was some flowing. In the morning the os uteri admitted two fingers, and the placenta previa was found laterally attached. The cervix was dilated manually, and the large boy baby safely delivered by podalic version. The loss of blood would have been large even for one who had a good supply. The bilateral lacerations of the cervix and the lacerated perineum were sutured, and there was no further hemorrhage, but she died eight hours after her delivery. She complained of great abdominal distress which was not accounted for. There was no autopsy. I have since questioned if the uterus was not ruptured. In the following case it certainly was.

Mrs. S. had had many children, all easily enough. But one fine morning while in labor she fell to quarreling with a neighbor out in the yard. She fell to the ground, screaming with pain, and with greatest difficulty got back into her house. Her family physician, recognizing that she was doing badly, sent her in to the hospital, where, after several had seen her, I was finally called in consultation. She was then nearly comatose, surface cold, pulse thready and not countable at wrists. The only history available was that she had been complaining of severe and continuous abdominal pain. There was a slight bloody discharge from the vagina, the os uteri admitted my half hand, but the child could not be found. The diagnosis was plain. And the patient was hurried to the operating table, where my colleague, Dr. H. A. Wood, opened the abdomen. There was immediate escape of blood and clots. The child's head was found protruding into the abdominal cavity through a side rent of the uterus which was afterwards found to extend through the broad ligament so as to bare the pelvic bones. The dead child was pulled out and then the whole uterus removed. Her recovery was tedious but complete.

I have reserved for the last my two most shocking disasters, two cases of death from pulmonary embolism. In my previous reports I had also the same misfortune. Four such deaths in 1,100 cases must be unusual. The question is, were they preventable? I cannot claim that I recognized the danger as I should to-day, which means that proper precautions were not taken.

The first case was a primipara, Mrs. H., nineteen years old, who was normally delivered of an 8-lb. daughter in February, 1899. For the first week she did very well and then began having irregular chills and fever. I could find no cause for it. Her only complaint was of pain in the left leg and thigh. There was no sign of phlebitis. For several weeks this condition continued, and then before the fever or the pain wholly left her I made the mistake of letting her sit up. A few days after, while sitting in her chair reading the newspaper, she suddenly screamed, turned black, and died, before the nurse could call for help even from the household. The autopsy showed a thrombosis of the left iliac vein and an embolism of the pulmonary artery.

My second case, Mrs. L., aged thirty-three, was a dear friend and neighbor whom I had previously delivered five times. After twenty-four hours of ineffectual labor I completed the dilation of the os and, finding a hand presenting, delivered by podalic version a 9-lb. boy. Both mother and child seemed to be doing very well, except for a slight unexplained fever in the mother and some pain in her left thigh. I did not mean to let her sit up, but I carelessly had allowed her to use the commode instead of bedpan. On the fifteenth day, when sitting there, she shrieked that she was dying and turned black. A few minutes afterwards I found the faithful nurse performing artificial respiration on the corpse. There was no autopsy, but there cannot be any doubt of the diagnosis. The lesson of it is that in cases of pain in thigh or leg, where even slight fever is present, we should suspect trouble in the iliac veins, and employ the same precautions as in phlebitis of the femoral.

---

The new Minnesota State Hospital for the Criminal Insane at St. Peter was formally opened on May 23, fifteen patients from the hospital at Fergus Falls being transferred to it. — *Med. Record.*

## HEXAMETHYLENAMINE AS A POSSIBLE PREVENTIVE OF PNEUMOCOCCUS EMPYEMA.

BY F. C. SHATTUCK, M.D., BOSTON.

THE very marked effect of hexamethylenamine upon the typhoid bacillus in urine; the fact that formalin seems rapidly to permeate the body fluids and tissues; the fact that the pneumococcus appears to be of less general resistance than some other organisms; and, further, the fact, as determined by Dr. Roger Kinnicutt, that very dilute solutions of formalin, 1 to 12,500, inhibit the growth of the pneumococcus in milk, afford an obvious suggestion that possibly pneumococcus empyema might be prevented by the routine administration of hexamethylenamine in cases of pneumonia. I was thus led a year ago to direct that every patient with pneumonia entering my wards in the Massachusetts General Hospital should receive the remedy. It was also given to some of the patients of my colleague, Dr. Gannett, and Drs. Kinnicutt and Barker have been so kind as to use it in their services in the Presbyterian Hospital of New York and in the Johns Hopkins at my request, in order that a larger mass of evidence drawn from different sources might be secured. To these gentlemen I wish to express my obligation.

From March 1, 1910, to March 1, 1911, fifty-nine cases of lobar pneumonia were treated with hexamethylenamine in the medical wards of the Massachusetts Hospital. This number includes only cases in which the diagnosis seemed assured. The drug was given as soon as the diagnosis was made, and the dose was 10 gr. three times a day, continued until death or well into convalescence. In three cases of young children the dose was proportionately less. The duration of illness before the drug was given varied from one to sixteen days, averaging five and one-half days. The duration of the hexamethylenamine treatment averaged twelve days. Three of these cases developed empyema.

In the first, a girl of six, the drug was given only after the temperature had fallen by lysis nearly to the normal, nine days after the onset. The pus showed pneumococci and that resulting from the operation later a few streptococci with pneumococci predominant. Recovery followed operation.

The second patient had been ailing for two or three weeks, but it was thought probable that the pneumonia began three days before entering hospital. After twenty-six days of continuous hexamethylenamine, pus containing pneumococci, streptococci and a trace of formalin was withdrawn from his chest. The patient recovered.

The third case began hexamethylenamine four days after the onset of pneumonia and continued it throughout his stay in the hospital. After twenty days, there still being signs of consolidation and slight temperature, a needle was introduced and a few drops of bloody, purulent fluid were withdrawn, showing streptococci in culture. The patient gained, soon felt very well and refused to remain longer under observation, so he was discharged without operation and lost sight of.

Of these three cases one is open to no objection, the second. In the first case, from an oversight, the drug was not given until the ninth day of the disease and pus was found four days later. In the third case the few drops obtained by aspiration seemed to be only blood until the microscope showed them to contain pus also. I have not been able to trace the patient. I do not know whether he really had an empyema or not. I include these two cases wishing to be too honest rather than credulous.

During the same period, there were forty-six cases of lobar pneumonia treated without hexamethylenamine. Three or four of these were not given the drug because moribund when brought to the hospital, and in one the pneumonia was a terminal event in chronic nephritis. In general, however, the cases were of the same class as those comprising the hexamethylenamine series. There was no selection of cases for the treatment. Of this number only one developed empyema.

In the preceding year, March, 1909, to 1910, of one hundred and forty-two cases of lobar pneumonia without hexamethylenamine, three developed empyema. Excepting in one doubtful case, no urinary disturbance could be attributed to the hexamethylenamine, although the average finding of albumin and casts was higher in the hexamethylenamine cases than in the others, as is shown by the following table:

| Year beginning March 1. | Without Hexamethylenamine. 1909. | 1910. | With Hexamethylenamine. 1910. |
|---|---|---|---|
| Number of cases examined, | 127 | 43 | 58 |
| Negative findings, | 32 (25%) | 8 (18+%) | 5 (9−%) |
| Very slight trace albumin or few hyaline or granular casts, | 81 (64%) | 17 (40%) | 32 (55%) |
| T. or L. T. or many hyaline or granular casts, | 10 (8−%) | 12 (30−%) | 15 (26−%) |
| Same plus blood free or on casts not accounted for by cta., etc., | 4 (3+%) | 5 (11+%) | 6 (10+%) |

Pericarditis, which complicated 4 or 5% of the non-hexamethylenamine cases in both years, was not observed in the hexamethylenamine series. The same is true of otitis media, which occurred in 3 to 4% of the cases not under the drug.

The mortality of cases in the hexamethylenamine series (20%) is a little lower than in the other series (25% in 1909 and 26% in 1910); but if we do not count the cases which did not receive hexamethylenamine because they were moribund, the mortality of the hexamethylenamine series would be as great or a little greater than that of the others.

The Johns Hopkins experience, kindly forwarded me by Dr. Boggs, is as follows: Between April 6, 1910, and Jan. 24, 1911, thirty-four cases

| Year beginning March 1. | Without Hexamethylenamine. 1909. | 1910. | With Hexamethylenamine. 1910. |
|---|---|---|---|
| Number of cases, | 142 | 46 | 59 |
| Recovered, | 106 (75−%) | 34 (74−%) | 47 (80−%) |
| Died, | 36 (25+%) | 12 (26+%) | 12 (20+%) |
| Died after two days or less in hospital, | 20 (14%) | 7 (15+%) | 3 (5+%) |
| Mortality, % excluding these, | 11+% | 11−% | 15+% |
| Empyemas, | 3 (2.11%) | 1 (2.17%) | 3 (5.08%) |
| Pericarditis, | 7 (4.9+%) | 2 (4.3+%) | 0 |
| Otitis media, | 4 (2.8%) | 2 (4.3%) | 0 |

of acute lobar pneumonia were treated with 10 gr. of hexamethylenamine three times a day, continued well into convalescence, the drug being started as soon as the probable diagnosis was established. In six of these thirty-four cases empyema developed. During the year April 1, 1909, to 1910, thirty-five cases of lobar pneumonia were treated without hexamethylenamine, empyema developing in only one. Both Dr. Barker and Dr. Boggs share the feeling that the incidence of empyema varies greatly from year to year, point with regard to which I have no facts on which to base an opinion. They add that in no case of their series is damage to the kidney, attributable to the drug, recorded. Messrs. Nichols and Orr, fourth-year students working in the medical clinic of the Johns Hopkins, have, after the administration of hexamethylenamine, demonstrated its presence in empyema pus, in pleural effusions and in ascitic fluid.

Dr. F. P. Kinnicutt has also kindly collaborated. Of twenty-five pneumonias under hexamethylenamine, one developed empyema. Of one hundred and ninety-three who did not take it, five had empyema. This complication, therefore, was more frequent in those who took the drug, but the number of the latter is very small. In none of the hexamethylenamine cases was pericarditis noted, though it occurred in 1½% of the others. I wish to thank Dr. Patton, house physician at the Presbyterian, for his help in this quest.

The results above reported are certainly not encouraging to the hope that in hexamethylenamine we may have a preventive for empyema, one of the most frequent, and, from the point of view of the comfort of the patient, the most serious sequelæ of pneumonia. These results, however, suggest that this drug may be a preventive of pericarditis and otitis media. Of course, it may be a mere coincidence that neither of these complications developed in the hexamethylenamine cases, but the contrast between the two series leads me to continue the use of the drug, and thus perhaps to arrive at more definite conclusions.

## "FIBROSITIS" AS A CAUSE OF CHRONIC HYPERTROPHIC SPONDYLITIS, AND POSSIBLY WITH A HERETOFORE UNDESCRIBED SIGN IN INTESTINAL AUTO-INTOXICATION.

BY N. S. YAWGER, M.D., PHILADELPHIA.

(*From the Department of Neurology in the University of Pennsylvania.*)

Having studied a considerable number of cases of chronic "rheumatic" myositis [1] and having observed in these cases many instances where the skin, fasciæ, fat and periosteum as well as muscles were involved, and also finding tenderness and stiffness quite commonly present about the spine in many persons in whom other parts were affected, it has seemed to me that chronic hypertrophic spondylitis is often but the spinal localization of a very common general condition, and which, in a mild degree, is quite frequently present. In many instances these various manifestations appear to have a common cause, this being auto-intoxication of intestinal origin. Indeed, such an origin for arthritis deformans has been frequently mentioned by writers, and notably in this country by McCrae,[2] Richardson[3] and Goldthwait,[4] but perhaps heretofore it has been more conservatively expressed.

That this hypertrophic spondylitis existed in the ancients is proven by the adventitious osseous formations found about the spine in skeletons that have been preserved through ages; and that this arthritis is of undoubted frequency in a varying degree is readily proven by the condition being observed in the dissecting-room and by the common appearance of spurs and more extensive osseous formations about the spine as shown by skiagraphs.

Frequently these spurs are so placed as to give rise to no symptoms whatever, but they may interfere with the spinal articulations and at times even impinge upon nerve roots. And depending chiefly upon this nerve root impingement, two types of so-called rhizomelic spondylosis were described. When nerve root symptoms were prominent, the case belonged to the group described by Von Bechterow;[5] if the nerve roots escaped or were but slightly impinged upon; we had the type of Marie-Strumpell,[6] where to the spinal affection was added involvement of some of the major articulations. The difference between these types depended largely upon the site and extent of these adventitious osseous formations. It would seem, then, that, in addition to these two types, many irregular forms might be expected, and this is in accordance with a large number of cases that have been reported. There really are no distinct types of the disease. The feeling of the most careful observers is that the term "chronic hypertrophic arthritis" is the best heading under which to group these various forms.

In an endeavor to maintain my former statement, that I believed hypertrophic spondylitis often to be but part of a very common general condition, I shall go back to the earliest literature obtainable upon this subject. About 1816, Balfour,[7] an English physician, was treating many gouty and rheumatic patients by friction, compression and percussion; he believed the trouble to be chiefly resident in the connective tissue, but

I do not know of his having found and described the indurations of which mention is now to be made. It probably was Froriep [8] who first recognized thickenings of this nature in the periosteum, although I am not aware of his having observed any special areas along the spine. Froriep spoke of these thickenings as *rheumatische Schwiele*, and found the condition present in the skin, fasciæ, muscles particularly, and in the periosteum. But few persons appear to know of a highly instructive volume by this German physician, published in Weimar in 1843, and in which he gives most careful clinical records of these "rheumatic" areas in more than eighty cases, telling of their development in many parts of the body. He labored a long time to establish the diagnostic value of the "rheumatic" induration. Froriep said,[9] "To find a new and hitherto undescribed symptom in a complaint of such common occurrence seems nearly impossible; yet in other things how frequently it happens that something is pointed out which has escaped previous observation, and then every one is surprised that he should never have noticed it!" More than half a century has elapsed since then and we are only beginning to recognize its importance, and although for more than fifty years the Swedes have had excellent manual methods for the removal of these areas, it remained for Edinger,[10] the German neurologist, to impress upon the profession outside of the Scandinavian countries the importance of these areas in the production of headache. This physician never failed to acknowledge the debt he owed to the Swedes, from whom he learned of this condition. And, strangely enough, Norström, one of the Swedish physicians whom Edinger mentions, spent some time in this country a few years ago, when he called our attention to the frequency of the condition and very explicitly explained to us the method of treatment. While here, Norström contributed a series of articles on massage to the New York medical journals, and considered the subject more scientifically than any American physician who has yet written upon the manual method of treatment. Unfortunately for us, we have not yet learned the lessons he taught.

For want of a better name, these areas have been termed "rheumatic," but not in the sense that they are the sequelæ of acute inflammatory rheumatism, although occasionally they may be. The term "fibrositis" suggested by Gowers [11] seems to be the best that has yet been offered, though special names indicating the sites of the indurations are useful. In this connection Gowers speaks of "cellulitis" and says, "But we apply the word to those conditions that are hyperplastic in nature and produce induration or suppuration. I think we need a designation for inflammation of the fibrous tissue which has no such results and yet, we cannot doubt, is of this nature. We may conveniently follow the analogy of "cellulitis" and term it "fibrositis."

A new and popular work says of the *induration* as a foci of *chronic myositis*, "But there are, as far as I know, no histological examinations on which to base such a term!" This pathology has been written about in Sweden, Germany, to some extent in England, and it has been discussed, though somewhat superficially, in this country. Briefly stated as typified by involvement of the muscular structure, there is in the beginning a serous exudate, or, in the more severe cases, a serofibrinous exudate; in the chronic areas, an increase in the intermuscular connective tissue and round cell invasion is observed, while the muscular fibers frequently show more or less distortion.

Of course it is important to distinguish between a stiff back due to adventitious osseous formations and that due to chronic muscular rheumatism, and this may be done with the administration of an anesthetic, when the latter condition yields readily, while the former remains unchanged. A skiagraph will also help to clear up the diagnosis.

Somewhat analogous, though resulting from an acute disease, is the frequent development of typhoid spine in cases of typhus abdominalis; from the careful observations of McCrae [12] and others, this spinal condition seems to be largely a spondylitis.

The upstart and irregular school of mechanotherapy styled "chiro-practic," which, theoretically at least, differs from osteopathy, claims as a basis for its work a partial occlusion of the intervertebral foramina through displacements of the vertebræ; they make the ridiculously absurd assertion that this is the cause of over 90% of all diseases. It may be that quite often there is present a slight constriction at these foramina, but I feel that this is most probably due to proliferation of the periosteum ("fibrositis") surrounding these openings and giving rise at times to nerve root symptoms. Long,[13] at a necropsy upon a patient who had died of pellagra, actually found this condition present and was unable to pass a Japanese toothpick through foramina which should have admitted a much larger body; radiographs from other patients likewise showed involvement of the spinal foramina. Others have observed the same narrowing of these orifices in spondylitis deformans. The ligaments are sometimes involved and osseous formations have also been found within the vertebral canal.

Many years ago, Geheimerath Oldevig was conducting a private institute at Dresden; his treatment consisted of the manual method and hydrotherapy. He was most painstaking in his work, often spending hours in the physical examination of a patient. For his exceptional skill he was accorded the highest medical honor that was bestowed by the king of Saxony. Oldevig repeatedly called the attention of his pupils to the presence of tender and thickened areas on the lateral aspects of the lumbar vertebræ, in patients who had suffered long from chronic indigestion. Upon palpation, I have found a thickening of the periosteum, with tenderness about the dorsolumbar spine, in a number of patients who have shown the symptoms of intestinal auto-intoxication. The abdominal symptoms which these cases usually present are constipation, flatulency

and often more or less tenderness and rigidity of the abdominal wall; after this rigidity has been overcome by skillfully performed massage, deep pressure will then usually reveal the presence of very tender areas within the abdominal cavity; to me, the exact location of these areas is an exceedingly interesting problem, and the fact that they can often be removed by massage, thereby causing a marked improvement in the general condition of the patient, should be a matter worthy of our most serious consideration.

Undoubtedly the thickened and tender areas upon the vertebræ often undergo absorption, but if they recur, and remain sufficiently long, there may be proliferation of the periosteum, leading to the osseous formations seen in skiagraphs and met with in the cadaver, and which we know are most common in the dorso-lumbar region of the vertebral column. So far as I know, this observation has had no special mention in medical literature, but it is possible that Rose [14] has observed the same local condition in women suffering from backache; he speaks of this as being due to a chronic periostitis of the spinal processes, generally of the lumbar or sacral, and asserts that the affection is easily recognized by pressure with the finger along the spine; he further states that he has had over thirty years' experience with this particular affection, but, except Dr. A. Jacobi, who first called his attention to it, that he knows of no physician who has written or spoken about it. He asks how many women may be treated, often heroically, for uterine trouble who suffer from this chronic periostitis.

It is interesting to note the association of this subject with dentistry; dentists have long known of the occurrence of pyorrhea alveolaris in persons who were either gouty or rheumatic. In some of these cases osseous formations have appeared upon the teeth; sometimes they are known as calculi, and other forms are scaly in nature. When we recall that the teeth form articulations with the alveolar sockets, and that the roots of the teeth are covered by a modified periosteum made up of fibrous tissue, it is not surprising that a "fibrositis" should be set up in this membrane and at times lead to the development of osseous formations similar to those found along the spine and about other articulations.

The disease, otosclerosis, meaning a progressive middle-ear disease in which the chief pathologic feature is the formation of an osseous deposit, in some subjects may be due to this condition.

It appears that the usual factors concerned in the formation of these areas may be trauma, refrigeration and dampness, and perhaps some poisonous substance elaborated within the body.

Because of the number and variety of movements which the spine is called upon to perform, this part is particularly liable to injury; we know that the lumbar and cervical regions of the spine have the greatest range of mobility, and these are sites where hypertrophic osseous tissue so frequently develops, admitting the presence of some poisonous substance in the circulation, it could readily cause irritation of this injured tissue, and if continued sufficiently long, lead to hypertrophic bony formations. The artificial production of callus by the injection of fibrin beneath the periosteum has recently been reported by Bergel,[15] and a familiar example of the ease with which osseous tissue is produced is recalled in the callus that forms after fracture.

The effect of cold and dampness is such a common experience, as when a cold draft strikes the back of the neck, and the pain and stiffness which follows unfavorable weather conditions, as to need but little mention. This effect is by no means limited to the muscles, for the periosteum is frequently involved. I am aware of the incredulous attitude of some physicians towards such effects from refrigeration; but how illogical for such an one to admit that he has not even recognized the condition of indurative headache, "perhaps the most common form of headache."

As to the presence within the body of some circulating poisonous substance, I recall a number of instances in which indurations in the skin, fasciæ and muscles were being broken up by vigorous massage, where the patient failed to keep up good elimination through the bowel, kidneys and skin, that headaches were felt, and neuralgic and rheumatic pains complained of in different parts. In one case which I have referred to elsewhere,[16] a typical attack of gout in the metatarso-phalangeal articulation of the great toe appeared to be precipitated in this way; the pain, redness and swelling, which developed so suddenly, had never been experienced before, nor has it been followed by any similar attack. It is true that no such poisonous substance has yet been isolated, but it may be similar in nature to some of the toxic matter which we believe so often slowly produces general arteriosclerosis. These cases frequently have arteriosclerosis before old age overtakes them, and the change in the vessel walls in the first stage of arteriosclerosis is similar to that so often observed in the chronic indurations met with in the connective tissue in many parts of the body.

Another possible cause, and one worthy of most careful consideration, is micro-organisms; and it may be that, later, various organisms will be shown to be directly responsible for the development of some of these indurations.

These various causes may or may not all be responsible for the production of hypertrophic osseous tissue present about the spine; but that a thickening exists, and that tenderness and sometimes pain can be elicited by pressure with the fingers over these areas, there is no doubt; and, finally, if these areas are not absorbed, I believe they often lead to the adventitious osseous tissue seen in skiagraphs and met with at necropsy.

The study of this low-grade inflammation in the connective tissue is big with possibilities. Its importance in the muscular system alone may be realized when a recent writer [17] considers it "an every-day affection" and says, "So much for a brief historical survey of what I consider to be the most neglected subject in the English literature of to-day."

## THE TREATMENT OF GASTRIC HYPERACIDITY WITH HYDROGEN PEROXIDE.

BY G. W. HALL, M.D., BOSTON.

*(From the Out-Patient Department of the Massachusetts General Hospital, Service of Dr. A. K. Stone.)*

IN 1908 Petri published the result of his investigation upon the influence of $H_2O_2$ upon the secretion of HCl in the stomach. He found that the administration of 300 ccm. of a $\frac{1}{4}$ to $\frac{3}{4}$% solution of $H_2O_2$ in cases of gastric hyperacidity with pain led to a disappearance of the pain, together with a marked decrease in the amount of HCl, even to its complete absence.

It is well known that sugar decreases the amount of HCl present in the stomach, while oil exerts even a greater effect, but Petri found a much greater decrease after $H_2O_2$ than after sugar or oil. Although, according to v. Alder, with a decrease in the amount of HCl there is a corresponding loss of pepsin, Petri found no diminution in the pepsin when the HCl had been markedly reduced by the $H_2O_2$.

His results have been fully confirmed by Goodman, Poly and Kato.

Goodman gave $H_2O_2$ to eleven patients with excellent results. He used a teaspoonful to a glass of water, approximately 200 ccm. of a $\frac{1}{2}$% solution. In every case the symptoms disappeared and the amount of HCl was much diminished.

Poly, in a very thorough investigation, using 300 ccm. of a $\frac{1}{2}$% solution, found a rapid disappearance of symptoms with decreased amount of HCl in mild cases (.17 to .22%) after three or four doses, and in severe cases (.24 to .36%) after ten to fourteen doses. Only two patients requiring more than fourteen doses.

That the effect is not permanent is shown by the fact that in one case where there was no free HCl after taking $H_2O_2$, this returned in ten days to .05% and in three weeks to .10, where it remained. The symptoms do not return, however, at least for a long time, one patient being entirely free from pain after one and one-half years.

Both Petri and Poly substituted Merck's magnesium perhydrol, for a solution of $H_2O_2$ with practically equally good results, Poly finding that some persons objected to the taste of the water solution gave the $H_2O_2$ in milk of almonds.

Kato's work corroborates that of former investigators, but he also found an increase of HCl where it had been previously absent. He used, in most of his experiments, oxygar, a combination of $H_2O_2$ and agar.

There is considerable doubt as to the manner in which the $H_2O_2$ produces these results. Both Petri and Poly found an increased secretion of mucus after its administration and ascribe the decreased HCl to neutralization by the alkaline mucus.

Togami in animals found an increased secretion of mucus, as did Kocco. But, as Goodman points out, an increase in the alkaline mucus cannot account fully for the result because the HCl secretion remains low after the $H_2O_2$ is stopped.

This method of treatment was tried in 30 cases during the service of Dr. Stone in the Out-Patient Department of the Massachusetts General Hospital.

We selected those patients who complained of distress or pain, referred to the stomach with other symptoms of hyperacidity. In the majority of our cases the percentage of acid is little if any above normal, but they were regarded as hyperchlorhydria where the normal or more acid was present with burning pain or distress coming on some time after eating, or where there were typical hunger pains.

Owing to the difficulty in getting patients to submit to a test meal or to subsequent test meals, the cases have been divided into three groups. In Group 1 are included those who had an initial test meal with subsequent test meals after taking hydrogen peroxide; in Group 2 those who had an initial test meal without subsequent stomach examination; and in Group 3 those who were treated wholly symptomatically.

In every case but one there was some degree of constipation which was treated by giving the patient a teaspoonful of Carlsbad salts in a glass of hot water before breakfast. A teaspoonful of $H_2O_2$ in a glass of water was given after each meal, and the patients told to eat three meals a day, and anything they wanted.

In judging results, attention was directed chiefly to the symptoms, the patient's own word being taken as to whether he was worse, better, or well; to the gain in weight; and in Group 1 to the change in the amount of hydrochloric acid present.

Group 1 includes fifteen cases. In every case but one the hydrochloric acid, both free and combined, was diminished after taking the peroxide. In three cases, there was no free HCl. In every case but one there was a gain in weight of

Group 1.

| Case. | Stomach symptoms. | HCl before treatment. | HCl after treatment. | Weight before. | Weight after. | Difference. | Results |
|---|---|---|---|---|---|---|---|
| 1. | Pain relieved by food. Gas. | .10 .28 | .07 .16 | 179 | 181 | 2 | Entirely relieved. |
| 2. | Severe cramps and dull boring pains. No relation to food. | .27 .30 | .21 .30 | 125 | 131 | 6 | Entirely relieved. |
| 3. | Severe continuous pain. Temporarily slightly relieved by food. G +. | .29 .34 | .22 .40 | 165 | 163 | 2 | No benefit. |
| 4. | Pain temporarily relieved by food. Much gas. | .16 .26 | None .21 | 134 | 137 | 3 | Entirely relieved. |
| 5. | Pain relieved by food. Sour eructations. | .18 .32 | .12 .21 | 121 | 122 | 1 | Entirely relieved. |
| 6. | Burning pain two hours p. c. relieved by food. Vomiting. | .14 .37 | .14 .25 | 128 | 129 | 1 | Entirely relieved. |
| 7. | Gnawing pain relieved by food. Tarry stools. Ulcer. G −. | .28 .36 | .23 .29 | 174 | 175 | 1 | Entirely relieved. |
| 8. | Dull gnawing pain partly relieved by food. | .11 .28 | .10 .23 | 135 | 145 | 10 | Better. Medicine not taken regularly. |
| 9. | Pain relieved by food. Gas G −. Inactive ulcer. Tarry stools. | .16 .24 | None .25 | 128 | 132 | 4 | Entirely relieved. |
| 10. | Continuous vomiting. Pain partly relieved by food. | .24 .28 | .09 .21 | 168 | 179 | 11 | Entirely relieved. |
| 11. | Gas and pain at first relieved then increased by food. | .16. 40 | .18 .29 | 141 | 152 | 11 | Very much better. |
| 12. | Gas and vomiting. Pain partly relieved by food. | .25 .30 | None .28 | 134 | 136 | 2 | Very much better. |
| 13. | Continuous pain. Burning sour eructations. | .11 .27 | .04 .14 | 150 | 155 | 5 | Entirely relieved. |
| 14. | Pain partly relieved by food. Much gas. | .49 .72 | .18 .25 | 140 | 149 | 9 | Very much better. |
| 15. | Pain two hours after meals. Vomiting. | .20 .40 | .12 .24 | 187 | 198 | 11 | Entirely relieved. |

from one to eleven pounds, the average being about six and one quarter. Ten patients reported an entire relief from their symptoms, three were very much improved, and one better. The latter, Case 8, did not take the treatment regularly. Case 3 appeared worse, if anything, with no diminution of the hydrochloric acid, and a loss of two pounds in weight. This patient had an active gastric ulcer with constantly positive guaiac test and marked mental symptoms.

Cases 7 and 9 both had inactive ulcers. They gave a history of tarry stools, and both had some degree of gastric stasis, but at the time they came under treatment neither gave a positive guaiac test with either gastric contents or stools. Both were entirely relieved by the peroxide.

Group 2 consists of ten cases. While an initial test meal was given, for various reasons no subsequent examination of the stomach contents was made. In every case there was a gain in weight of from one to seven pounds, the average being three and two-fifths pounds. Seven cases were entirely relieved and two were very much better.

Case 5 was not benefited. This patient undoubtedly had an active gastric ulcer with a positive guaiac test.

Group 3 consists of five cases, whose symptoms were those of hyperacidity. No examination of the stomach was made.

Each patient gained in weight from five to twelve pounds, the average gain being seven pounds.

Three patients were entirely relieved and two were very much better.

In connection with Case 3, Group 1, and Case 5, Group 2, both of whom had active gastric ulcers and were unimproved, it is interesting to note that Nowikoff suggests the failure to improve after taking hydrogen peroxide as a means of differential diagnosis between ulcer and hyperchlorhydria.

Group 2.

| Case. | Stomach symptoms. | HCl | Weight before. | Weight after. | Difference. | Results. |
|---|---|---|---|---|---|---|
| 1. | Pain. Gas. Vomiting. | .21 .25 | 129 | 136 | 7 | Entirely relieved. |
| 2. | Gnawing pain relieved by food. Vomiting. | .14 .22 | 159 | 162 | 3 | Entirely relieved. |
| 3. | Vomiting. Pain at first relieved then increased by food. | .19 .28 | 118 | 119 | 1 | Very much better. |
| 4. | Pain begins one hour p. c. Continuous at night. | .13 .27 | 146 | 149 | 3 | Entirely relieved. |
| 5. | Pain relieved by food. Cramps. Gas. G +. Ulcer. | .17 .25 | 145 | 146 | 1 | Unrelieved. |
| 6. | Pain and cramps. Gas. | .16 .27 | 137 | 142 | 5 | Entirely relieved. |
| 7. | Continuous sharp pain. Gas. | .24 .33 | 145 | 148 | 3 | Entirely relieved. |
| 8. | Dull gnawing pain. | .10. 21 | 132 | 134 | 2 | Very much better. |
| 9. | Pain uninfluenced by food. | .18 .45 | 161 | 166 | 5 | Entirely relieved. |
| 10. | Continuous pain worse at night. Gas. | .22 .38 | 170 | 174 | 4 | Entirely relieved. |

Group 3.

| Case | Stomach symptoms. | Weight before. | Weight after. | Difference. | Results. |
|---|---|---|---|---|---|
| 1. | Gnawing pain relieved by food. Gas. | 144 | 149 | 5 | Entirely relieved. |
| 2. | Burning pain. Sour eructations. | 154 | 160 | 6 | Entirely relieved. |
| 3. | Gnawing pain relieved by food. Gas. Vomiting. | 134 | 146 | 12 | Entirely relieved. |
| 4. | Gnawing pain relieved by food. Vomiting blood. Ulcer. | 196 | 201 | 5 | Very much better. |
| 5. | Gas with sharp pain and occasional vomiting. | 154 | 161 | 7 | Very much better. |

CONCLUSIONS.

While the results here are not quite so good as those previously reported, they do show:

First, That $H_2O_2$ diminishes the amount of hydrochloric acid in the stomach.

Second, That those patients with hyperchlorhydria get great or total relief from their symptoms.

Third, That there is a gain in weight.

Fourth, That it does not appear to benefit cases with active ulcer; and

Fifth, That this method of treatment is a useful addition to the methods already in use, in the treatment of hyperchlorhydria.

## Clinical Department.

### A CASE OF VERTIGO CURED BY TREATMENT OF THE EUSTACHIAN TUBE.*

BY EDGAR M. HOLMES, M.D., BOSTON.

IT has been known and generally accepted for a long time that vertigo may be due to middle ear conditions depending upon a diseased tube. Many such cases have been observed and reported.

This case I am reporting is of special interest in that the symptoms were severe and of long duration while under the usual treatment and because so few treatments of the Eustachian tube entirely relieved the condition. It was diagnosed by the men on duty at the Boston Dispensary six months before I saw the patient as one of probable middle ear origin, as the tests for labyrinthine disease were not present.

Dr. Inglis, who first examined this patient, saw her after she had been dizzy for three months, and her condition had grown progressively worse. She was fifty-two years old and married, and her first symptoms began sometime in March of 1910. Following a cold in the head she became quite deaf for a few days and there was also a feeling of fullness in both ears, there was also slight pain in the left ear. A low rumbling tinnitus began about one week after the first symptoms and continued for a number of weeks, when it gradually subsided. There was slight vertigo noticed soon after the beginning of the ear symptoms, and this condition grew gradually worse. The patient was compelled to carry the head perfectly level and could not look down upon the street nor stoop to lace her shoes without a violent attack of vertigo. She had the feeling of pitching forward.

When she was first examined at the Dispensary it was found that both membranæ tympani were retracted and thickened.

The records show that she was treated regularly by catheterizing the Eustachian tubes from Sept. 8 until Jan. 5, when I first saw her. There had been no apparent improvement, temporary or permanent. As the patient entered the room her effort to maintain her equilibrium was apparent. She was well nourished but her expression was somewhat careworn. The pulse was 82 and normal. Both pupils reacted normally to light. The patellar reflexes were normal. The tongue was clean and she said she had no stomach or bowel trouble. I examined and found the same middle ear signs as had been found by Dr. Inglis six months before. Both membranæ tympani were retracted and thickened, but they were movable by Siegle's otoscope. The hearing was

| | | | | | |
|---|---|---|---|---|---|
| R | $\frac{a}{b}$ 18 | 20 | $\frac{a}{14}$ | 21 | |
| | C | C′ | C″ | C‴ | for forks |
| L | $\frac{a}{b}$ 16 | 19 | $\frac{a}{17}$ | 22 | |

and she could hear the whispered voice about four feet in either ear.

The Webber test was negative. The rotating and caloric tests were negative. An examination of the nose showed nothing abnormal, but the nasopharyngoscope showed an interesting condition in the nasopharynx.

The right Eustachian tube was moderately swollen and injected but apparently showed normal movements during deglutition. The left tube was much swollen, the blood-vessels were dilated and there was much restriction of the movements in the floor of the tube during deglutition. The posterior boundary of the left Rosenmuller's fossa was in contact with the cushion of the Eustachian tube, but there were no adhesions between them.

Inflation with the catheter produced a bulging of the membrane but gave no relief from the dizziness. I began making applications of argyrol within the tubes, more to see how much we could relieve the local inflammation than believing we could relieve the severe vertigo. These applications were made every other day and after the fourth application had been made the patient said that she was better than she had been for nine months. At the end of ten days the vertigo was gone and no movements of the head could produce an attack. She could stoop and pick up articles from the floor with no inconvenience. The swelling in and about the left Eustachian tube was very much reduced and the membranæ tympani had lost the marked retracted appearance.

The treatment was continued until March 16, for although there were no remaining symptoms, the mucous membrane of the tubes was somewhat swollen and inflamed. At the present time both Eustachian tubes are apparently normal and so far as symptoms go the patient is entirely well. The hearing has increased to

| | | | | | |
|---|---|---|---|---|---|
| R | $\frac{a}{b}$ 29 | 34 | $\frac{a}{14}$ | 32 | |
| | C | C′ | C″ | C‴ | |
| L | $\frac{a}{b}$ 25 | 31 | $\frac{a}{17}$ | 31 | and whispered voice to 10 feet. |

This case has been of particular interest in that the symptoms had grown worse under the usual treatment and had become so severe as to incapacitate the patient for all work and that so few treatments of the tube produced a cure. Without the aid of the 'scope it would have been impossible to have determined the condition of the tubes, neither could we have applied treatment directly under vision without some such instrument.

One important point in the treatment is to cause no trauma of the mucous membranes. The Eustachian applicator should be very carefully constructed and should be very gently pushed into

* Read at a meeting of the New England Otological and Laryngological Society, March 28, 1911.

the tube. By watching carefully the tip of the instrument as it enters the field of vision of the 'scope it can be directed as easily and gently as if it were being passed into a crypt of the tonsil under direct guidance of the eye. After it has entered the lumen of the tube it is under the direction of the sense of touch, but even then it is of importance to watch the tip of the catheter and see that it is kept in contact with the orifice of tube and that no undue force is brought upon it.

In regard to the best drugs for use in the treatment of inflammation of the Eustachian tube, our experience is too limited to say anything at all positively, but of those we have used we have found that a 15 to 20% of argyrol has given the best results, not only in the acute, but also in the chronic cases.

I do not believe that by this treatment we shall be able to relieve all cases of tubal inflammation, nor will it be likely that all chronic middle-ear diseases whether producing vertigo or not will subside when the tube has been restored to its normal functions, but what we can do is to examine and treat all cases under the guidance of the eye.

This is a great step forward and I believe we shall all achieve results which were impossible under previous methods.

## A CASE OF NERVE DEAFNESS DUE TO THE TOXEMIA OF DIABETES.

BY WM. H. MERRILL, M.D., LAWRENCE, MASS.

As the patient whose case will be reported tonight still has a use for his temporal bones, it would have been well for me to have asked our secretary to place an interrogation point after the title of this report.

An attempt will be made to convey as accurately as possible by words the symptomatology, but at best these will be unsatisfactory data from which to ask the members to agree or disagree with the diagnosis.

When first the diagnosis of a toxic neutritis was made, the writer had a feeling of disgust in having a patient under observation for eight weeks with obscure aural symptoms and not having made a diagnosis which seemed so easy after an urinary analysis had been done.

A later examination of such textbooks and journals as were accessible failing to reveal any mention of diabetes as a cause of auditory neuritis was something of a comfort. A number of writers mention a paralysis of the seventh nerve due to neuritis as an occasional complication of diabetes. The close proximity of the origin and preliminary course of the seventh and eighth nerves would suggest the possibility of a simultaneous involvement, but no facial paralysis was noted in the case of J. B., who was referred to me June 17, 1910.

Family history meager and negative.

Personal history of smallpox and scarlet fever before age of twelve. No pain or discharge from ears is remembered.

Present condition, male, age fifty-five, weight 160, attendant at a county institution. No general symptoms of sufficient importance to attract attention of the physician who referred him. Deaf in right ear twenty years; does not remember manner of onset, but thinks there has been no tinnitus. He was not aware of any deafness in left ear until morning of June 2, when was so deaf when awakened by member of family that only a shout could be heard.

There was no dizziness or nausea. A little dizziness on stooping had been noticed for a month previous to the attack. This is not present now. Patient was treated by Pollitzer inflation for a week or two by a general practitioner and a little improvement in hearing was noted during this time.

Both membranæ tympani moderately retracted and lacking somewhat in luster. The right has small area of calcareous degeneration. Both ears are readily inflated with catheter but without improvement in hearing.

Hearing test as follows:

| | Right. | Left. |
|---|---|---|
| Watch, | O. | C. less distinct on mastoid. |
| Voice, | Shout at 1 ft. | 5-40 (loud voice). |
| A. C., | 512 not heard. ? | 10. |
| B. C., | Not heard. | 5. |
| Lower, | 512. ? | 256. |
| Upper, | 1. | 1. |

.4 is normal on my Galton whistle. Rotation tests and hot water in left ear applied March 23, 1911, showed normal nystagmus.

Hearing tests were made at intervals of eight or ten days, which showed little change on the whole from the above, but it was noted that the perception varied much at different periods of the same setting. This variability being one of the symptoms mentioned by authors as denoting hysteria, a search was made for some stigmata or history of this disease with negative results.

About a month after coming under observation Dr. Amadon saw Mr. B. and cleaned out the fossæ of Rosenmüller.

July 20 an analysis of urine was made which disclosed a spg. of 1,035 and a large quantity of sugar, no albumin, quantity 4,009. At this time the patient would not admit to having symptoms of any illness. Treatment of ears was discontinued and he passed into the care of his family physician. When seen a month later there had been a loss of 10 lbs. of flesh and there was not the same appearance of good health.

On March 20 a part of the lost flesh had been regained. The hearing tests showed little change from the first one.

The loss of lower tones and the appearance of the membranæ tympani certainly indicates middle-ear deafness, to which I believe a nerve lesion to have been added.

Lack of vestibular symptoms point to involvement of the trunk of the nerve.

Probably it will be willingly agreed that the acetonurea of diabetes, in common with the toxemia of syphilis, influenza, malaria, etc., could easily produce a neuritis of the eighth nerve as of others which are rather frequently involved. The only lesson of importance the writer sees in this, perhaps rare case, is the necessity of always bearing in mind that grave systemic diseases often have their first manifestations in the organs of special sense, and we should be alert to recognize them. Patients frequently consult the oculist or aurist without visiting their family physician, or if they do ask advice of their physician, they

present slight or no symptoms of a beginning systemic disease which attracts attention.

The only reports in literature I have found were references furnished me by Dr. Shambaugh, and are as follows: Hegher, Zeitschrift für Ohrenheilkunds, vol, lv, page 111. An acute neurolabrynthitis which was characterized by the marked labyrinthine symptoms, vertigo, tinnitus and deafness. The patient had ½ of 1% of sugar in urine, which was eliminated by diet and recovery, but not complete in high times, followed.

Witmach, Zeitschrift, vol. liii, page 19. Autopsy findings in case of ten-year-old girl who died in diabetic coma which showed degenerative neuritis and atrophy of eighth nerve.

Witmach also mentions diabetes as a cause of auto-intoxication neuritis, Zeitschrift, vol. xlvi, page 1.

## LATERAL DEVIATIONS OF THE EXTERNAL NOSE.

BY A. COOLIDGE, JR., M.D., BOSTON.

VIEWED from in front, the line of the nose in a typical face is straight and symmetrical. Frequently, however, as a result of trauma or irregular growth, the nasal dorsum deviates either as a whole or in part from the middle line. These lateral deviations of the external nose may be grouped into three main types.

In the first, the whole nose deviates to one side, the dorsum is straight, there is no angle laterally between the upper bony and lower cartilaginous portions, but the tip is on one side of the median line. This type is due, at least for the most part, to asymmetrical growth.

In the second type the bony upper half deviates to one side, while the cartilaginous lower half tends to return to the median line, causing a lateral angle in the dorsum. This deformity is the same as occurs with a fracture or dislocation of the nasal bones, and when not due to recent trauma is generally the result of an old unreduced dislocation.

In the third type the nasal bones are in the middle line, while the cartilaginous portion is bent to one side. This may be developmental or it may be the result of old trauma of the quadrangular cartilage of the septum from a blow on the tip of the nose modified by subsequent cicatrization.

Two or more of these types of variation may be combined.

When the external nose deviates, there is necessarily also more or less deviation of the nasal septum. In traumatic cases the septum is bent as a result of the external violence. When the asymmetry is due to irregular growth, the deviation of the septum may be the primary cause of the external deviation. With the forward growth of the septum in adolescence it frequently becomes deviated or bent, and the external nose, bony as well as cartilaginous, follows the lead of the septum and adapts itself to the asymmetrical cavities within. This applies not only to the nasal bones, but also to the nasal processes of the superior maxilla, which, as they are joined to the whole lateral edge of the nasal bones, are practically one piece with them.

As a disfigurement, a lateral angle between the bone and the cartilage is of more importance than a deviation of the nose as a whole from the median line. For this reason, there is seldom any reason for correcting a deviation of the first type. Often a considerable degree of lateral displacement is not noticed if the line of the dorsum is straight.

In the second type, where the nasal bones deviate, and the lower half of the nose returns towards the median line, the problem is somewhat similar to the reduction of a recent dislocation, except that the bones must be broken or cut. The distance from the dorsum of the nose to the level of the cheek, that is, the combined breadth of the nasal bones and nasal process, is the same on the two sides if the nose is in the middle line, but different if it deviates to one side. In other words, in order to replace the dorsum into the middle line it is necessary to make the distance equal on the two sides. If the narrower side cannot be broadened this must be done by narrowing the broader one, by sliding the edge of one nasal bone under the nasal process. This necessarily somewhat lowers the dorsum, or, in other words, reduces the profile. It may therefore be said that if there is height to spare, the operation is a simple one. It may be done as follows: An incision one-eighth of an inch in length is made along the middle of the junction of the nasal bone and the nasal process on each side. Through this a chisel separates the nasal bones from the nasal processes as high as the neck of the nasal bones. Taking advantage of the mobility of the skin, the chisel is turned at a right angle, and cuts through the neck of the nasal bones. The nasal bones from the neck downwards are then freely movable. Then upon the broad side, the periosteum of the upper edge of the nasal bone and the lower edge of the nasal process is elevated, making a pocket into which the nasal bone is pressed, and held in position by a strap depressing the dorsum. The incisions are closed without sutures, they heal by first intention and leave no appreciable scar. Enough of the septum must be resected either before or at the time of operation to correspond to the reduced height of the dorsum.

A nose which is too high and prominent, but straight, may be reduced in height by the same operation, except that the nasal bones on both sides instead of only one are pushed under the nasal processes. The bones are generally so thin that no line along their point of separation shows through the skin.

For the third type of lateral deviation, when the bones are in the middle line but the cartilage is bent to one side, a resection of the cartilage must be done. As little cartilage as possible should be removed, to save the tip of the nose from sinking. Each case presents its own problems, which are often difficult, and the results may be endangered by unexpected cicatricial contractions.

## PLASTER CASTING FROM LIFE TO SHOW EXTERNAL DEFORMITIES OF THE NOSE BEFORE AND AFTER CORRECTION.

BY ISABELLE D. KERR, M.D.

Of the different methods for making plaster casts from life, there are three of value to us. These are the partial face, the complete face and the partial head cast, all of which have their special merits.

For the cast of a child or of a very nervous person where it would be difficult to get them to breath through respirators, the partial face cast is the only one obtainable. Also to make a cast just previous to operation where time is limited, this cast takes the least time, and gives one valuable help. The full face cast is the more ideal, however, as it shows a deformity of the nose in its proper relation and a deviation of the nose at its proper angle to the rest of the face. If care is not taken in trimming a partial face, or in the manner of holding the cast, it may be possible that the degree of deviation is not shown at all. Particularly is this true if the nose is straight, but deviating as a whole to one side. The partial head cast would be the ideal one for all purposes except for the time which it takes to complete it. This makes it less practical than the full face cast. With the partial head, one has the advantage of using the ears as landmarks, thus accurately seeing the degree of deviation. This would be the cast to make to show any asymmetry of the head.

The method for making these casts is as follows: The patient is placed in the recumbent position. The clothing protected with a sheet. The face is prepared by smearing it well with a thick oil. The eyebrows, eyelashes and hair near the forehead are well soaked with oil to keep the plaster from adhering when set. To keep the plaster from getting into the eyes, I have been covering the lids with cargyle membrane in some cases. In others I have used nothing but the oil because I found that with the cargyle I did not get a very sharp impression. Patients should be instructed not to open the eyes until all the plaster has been removed from the lashes after the mask has been removed. A few minutes for practice in breathing through the respirators before the plaster is put on does away with the patient's fear that he is going to be smothered.

For respirators, I use pieces of small rubber tubing about five or six inches long. These are inserted about one and one-half inches into each nostril, taking care that the tubing is placed along the floor of the nose in order that the alæ shall not be pressed out and cause a wrong impression of the nose. Before inserting the respirators, it is well to cocainize the nose to do away with the discomfort and irritation, and the desire to sneeze, caused by the respirators. Cocaine also renders the breathing comfortable. In these cases of external deformity where there is usually a corresponding internal deformity with difficulty in breathing through one or both sides of the nose, it would be impossible to get enough air through the respirators without first shrinking the tissues. When a respirator cannot be inserted into a nostril on account of deformity, it has to be placed in the mouth.

Absorbent cotton is placed in the ears and around the respirators to keep the plaster from running in. To keep the plaster from running on to the back of the head, a board shield is held by an assistant on either side of the head, about an inch in front of the ear for a partial or complete face, and just back of the ears for a partial head. For the partial face the sheet is drawn up over the mouth and held on the sides by the shields. This prevents plaster from getting into the mouth and allows the patient to breath through the mouth under the sheet.

The plaster is mixed to a thin consistency somewhat thicker than cream. The impression of the face is begun by first pouring a spoonful of this thin mixture about the nose. Plaster sets very rapidly and gives an accurate impression of the nose if put on thin enough so that it will run easily around the angles of the nose and between the respirators.

The next step is to put a thin layer over the ears if making a partial head, or on the sides of the face if otherwise, then the chin and lastly the eyes because by this time the plaster has thickened and is less liable to get into the eyes. Then a second layer of plaster is put on to give the mask strength enough so that it will not break when removed.

Also the first coat around the nose has set sufficiently by the time you are ready to put on the second layer to bear the weight of the second coat so that the tip of the nose will not be depressed from pressure and give a false mask. The mask is left on until the plaster is sufficiently hard to remove, which is done by slight rocking until free, then lifting off. The respirators come out with the mask. Any defect in the mask caused by the joining on of plaster while building it, is filled in with plaster. The mask is then washed in water, smeared with liquid soap, then paraffine and kerosene, in order to keep the face plaster from adhering. The plaster used for making the face should be a hard plaster so that it will not break easily, while that used for the mask should be soft so that it can be more easily chiseled away. The face plaster is mixed to the same consistency as for the mask, poured into the mask, smoothed off, and, when set, turned over, and the mask chiseled away. Any defect in the face is touched up. The face is then given a coat of white shellac, the purpose of which is to preserve the model. After the plaster has thoroughly dried out it is so easily soiled and scratched from handling or dusting that the features can be easily destroyed. Finally, the cast may be tinted.

---

The Italian *Policlinico* states that there is an endowment at Nice for bestowing small prizes annually on persons who have distinguished themselves particularly in "works of kindness and charity." Among the recipients at the recent distribution of the prizes last month was Count G. Naldi, dean of the physicians at Nice, aged ninety-one years.—*Jour. Am. Med. Asso.*

## REPORT ON PEDIATRICS.

### PHYSIOLOGY AND PATHOLOGY OF THE DIGESTION OF THE CARBOHYDRATES IN INFANCY.

BY JOHN LOVETT MORSE, A.M., M.D.,
AND
FRITZ B. TALBOT, M.D.

### PHYSIOLOGY. FERMENTS.

Zwiefel, 1874,[1] and Korowin, 1875,[2] were unable to find a diastatic ferment in the pancreas of newly born babies, and to this fact is due most of the misconceptions concerning the power of digesting starch in infancy. The work which corrected this impression will be quoted later.

*Saliva.* — Zwiefel [1] found diastase in the parotid gland of the newly born but was unable to find it in the submaxillary. Ibrahim,[3] after a prolonged piece of work, found it in both the parotid and submaxillary glands, its action being stronger in the former than in the latter. Diastase was found much earlier in fetal life in the parotid than in the submaxillary, traces being found in the former at the fourth and in the latter at the sixth month of fetal life. The diastase of the parotid is the earliest digestive ferment found in the embryo.

A diastatic ferment can always be found in the saliva of healthy infants.[4] The diastatic action of saliva may continue in the stomach as long as two hours after feeding.[5]

*Stomach.* — Ibrahim [3] is the only worker who has examined the gastric mucous membrane of the newly born for the carbohydrate splitting ferments, and he has been unable to find either lactase, maltase or invertin.

*Pancreas.* — Moro [6] was able to demonstrate the presence of an amylolytic ferment in the pancreas of newly born babies when the pancreas was thoroughly extracted, and thus disproved the earlier work of Zwiefel and Korowin. Ibrahim [3] never failed to get the ferment in a six months' fetus when he tested the action of the ferment on starch meal. He was, however, unable to find it when he tested soluble (i. e., cooked) starch.

Ibrahim was unable to demonstrate invertin and lactase in the pancreas of newly born or older babies, but he was usually able to demonstrate maltase in the newly born and always in older children. Maltase may also be found in the blood.

*Small intestine.* — The mucous membrane of the small intestine contains amylolytic ferments.

Lactase, the ferment which splits milk sugar, has been repeatedly found in the mucous membrane of the small intestine.[7] Ibrahim always found it in the small intestine and meconium of newly born babies, but was unable to find it in premature infants. He says, however, that his method of determining lactase is not capable of demonstrating small amounts. Lactase is more abundant in the young animal than in the adult.

Pautz and Vogel found maltase, the ferment which splits malt sugar, in the small intestine of infants.

Invertin, the ferment which splits cane sugar, was found in the secretions of the small intestine of the newly born by Miura,[8] and Ibrahim was always able to demonstrate its presence both in the intestinal mucous membrane and in the intestinal contents of all fetuses.

*Large intestine.* — It is difficult to wash the large intestine free from meconium, and the results of the examinations of its mucous membrane are variable, as the tables of Miura, Pautz and Vogel show. It is, therefore, impossible to say whether it contains ferments or not.

*Stools.* — Pottevin [9] found an amylolytic ferment in the meconium. Kerley, Mason and Craig [10] were able to demonstrate the presence of a strong amylolytic ferment in the stools of very young babies, the possibility of the bacterial fermentation of starch being excluded. There is a larger amount of diastase in the stools of breast-fed babies than in those of the bottle-fed, which Hecht [11] believes to be due to the fact that the intestinal contents of the breast-fed baby pass more quickly through the intestinal canal than do those of the bottle-fed baby.

The power of digesting starch, while occasionally absent, is, therefore, almost always present both in the fetus and in the newly born.[3,7,12] Hedenius' experiments show that it is less powerful in young babies than in later life. Young babies are, nevertheless, able to adapt themselves to a food rich in carbohydrates. There is, according to Moro,[14] a rapid increase in the power of digesting starch during the first week of life. The baby, therefore, has a power of digesting starch at birth which gradually increases in strength as the baby grows older. According to Finizio,[15] it is twice as strong at eight months as it is at birth, while at twelve months it is almost as strong as at three years.

The question whether the carbohydrate-splitting ferments are affected by disease has been answered only in part. Orban [16] found by animal experimentation that an injured intestinal mucous membrane contained no lactase, and that the stools of babies ill with enteritis contained no lactase. Langstein and Steinitz,[17] on the other hand, always found lactase in the stools of babies ill with enteritis, whether mild or severe, acute or chronic.

### FORMS OF CARBOHYDRATES.

The carbohydrates used in infant feeding may be divided into the groups [18] as shown on the following page.

There are various preparations of the starches, such as Mellin's Food, Malted Milk and Liebig's soup, which are more or less dextrinized.

Lactose, or milk sugar, finds its origin only in animals. The researches of Deniges [19] and Bonamartini [20] established the fact that the lactose in the milk of the woman, cow, ass, rabbit, dog and horse is essentially the same. Its quantity varies the least of all the elements of human milk.

### DIGESTION OF CARBOHYDRATES.

The carbohydrates are broken down during digestion into the simplest forms of sugar, the

| Milk sugar group. | Cane sugar group. | Malt sugar group. | |
|---|---|---|---|
| | | Starch (Amylum) | |
| | | ↓ | |
| | | Dextrin (Amylo-dextrin) | Poly-saccharide |
| | | ↓ | |
| | | Erythro -& Achro-dextrin | |
| | | ↑ | |
| Lactose (Milk sugar) | Saccharose (Cane sugar) | Maltose (Malt sugar) | Di-saccharide |
| ↕ | ↕ | ↕ | |
| Dextrose + Galactose | Dextrose + levulose | Dextrose + Dextrose | Mono-saccharide |

mono-saccharides, by the various ferments described above. According to Rohrmann [22] a considerable amount of the disaccharides may pass into the intestinal mucous membrane and there be split into mono-saccharides. The mono-saccharides are carried by the portal vein to the liver, where they are transformed into glycogen, the only difference being that dextrose is more easily converted than levulose or galactose.* The pancreas has some influence on this process, because extirpation of the pancreas in dogs results in sugar in the urine and interferes with the formation of glycogen in the liver. The liver actually has the property of forming glycogen from sugar.†

The purpose of the splitting of the poly- and di-saccharides into mono-saccharides is to prepare them for use inside the body, because the unsplit carbohydrates are not burned up in the body, but are excreted in the urine. The transformation of sugar into glycogen, which is deposited in the liver and muscles, is of great importance, because this glycogen can be broken down again into sugar according to the needs of the body. The mono-saccharides are absorbed more quickly than the disaccharides.[23]

A large part of the digestion and absorption of the carbohydrates takes place in the upper part of the small intestine,[24] but splitting and absorption may also take place in the large intestine.[25]

There is normally about 1-10% of dextrose in the blood. The slightest disturbance of the regulating apparatus will cause a hyperglycemia which results in glycosuria. A deficit of sugar in the blood is made up from the glycogen deposts.[21]

Albertoni [26] and Hédon [27] found that sugars have a purgative action when they are given in large enough amounts. This action is more marked when they are taken in concentrated solution. All sugars have this action, the difference between them being only in degree. They found that glucose and cane sugar are much more quickly absorbed than lactose, and that the former has less of a purgative action than the latter.

Little or no sugar can be found in the stools under normal conditions, but when the food passes rapidly through the intestinal canal, as it does when peristalsis is rapid as the result of disease or indigestion, sugar can be found in the stool (Hecht). Usually only the products of the decomposition of sugar can be isolated.

Hedenius [28] fed babies with milk mixed with wheat flour, oat gruel or Keller's malt extract and measured the amount of carbohydrate ingested, the amount in the stools, and their acidity. He found that when simple cereals were used, less carbohydrate was found in the stools than with complicated mixtures and that the more carbohydrate in the stool, the greater its acidity. He never found more than 3% of the ingested carbohydrate in the stool in any instance. Keller [4] has shown that carbohydrates make the digestion of protein more complete.

### METABOLISM OF CARBOHYDRATES.

Numerous observations [29] have shown that when milk sugar is injected directly into the circulation it may be completely recovered in the urine. Grosz [30] was never able to detect milk sugar in the urine of healthy babies, but found it in the urine of those suffering with gastro-intestinal disease, in which there was presumably an absence of lactase in the intestine. Langstein and Steinitz [31] repeated Grosz's experiments and in certain instances found lactase in the stools at the same time that sugar was being excreted in the urine. This sugar was, moreover, not always lactose, but sometimes galactose, one of the products of the splitting of lactose. They tried to explain this as follows: That some of the sugar passes through functional or anatomical lesions of the intestinal wall before it is completely broken up and is excreted in the urine as an intermediary product of metabolism.

Mendel and Kelimer [32] have shown that when cane sugar is introduced subcutaneously into dogs or cats in doses of one to two grams per kilogram of body weight it is not completely recovered in the urine. The quantity excreted amounts as a rule to more than 65% of that introduced. The excretion begins within a few minutes and is usually completed within thirty-six hours. Fisher and Moore [33] draw attention to the possibility that the sugar thus introduced may be excreted through the walls of the alimentary tract and there be digested. These views are supported by Japelli and D'Errico,[34] who conclude from their experiments on dogs that when cane sugar is introduced directly into the

* Abderhalden: Textbook of Physiological Chemistry, London, 1908.
† Grube: Pflüger's Arch. cvii, 1905, p. 490.

circulation the quantity eliminated in the urine is never equivalent to the amount injected. This causes both glycosuria and saccharosuria, the former disappearing first. The blood has no power of converting cane sugar. According to these writers, cane sugar introduced intravenously is eliminated into the alimentary tract through the gastric mucosa, the salivary glands and, to an insignificant degree, through the bile. The subsequent fate of this component is obvious.

According to Finkelstein [35] sugars may cause fever. This so-called sugar fever has been studied especially by his pupils. Leopold [36] found that 43% of the babies tested with lactose, 47% of those with glucose, 42% of those with saccharose (cane sugar), and 33% of those with maltose reacted with fever. This fever was always accompanied by diarrhea, and in none of the cases tested in which the stools remained normal did the sugar cause fever.

The limits of assimilation of the different sugars varies and are as follows:

Grape sugar: In babies, about 5 grams per kilogram (Langstein and Meyer).

Grape sugar: In one-month baby, 8.6 grams per kilogram (Greenfield [37]).

Galactose: No accurate data.

Levulose: (Lower for babies than adults.) One gram per kilogram (Keller).

Maltose: Over 7.7 grams per kilogram (Reuss).

Lactose: 3.1–3.6 grams per kilogram (Grosz).

Cane sugar: Probably about the same as lactose (Reuss).

Escherich [38] divides the digestive disturbances of infancy into two main types: (*a*) Fermentation with the formation of acid products and (*b*) putrefaction with the formation of alkalies. These two processes are antagonistic to one another, the basis of fermentation being carbohydrates and of putrefaction protein. An excessive preponderance of one over the other may do harm. Fermentation results in an excessive formation of acids, especially of lactic acid from lactose. This may cause a large number of stools as the result of the increased peristalsis and the flow of serous fluid or cellular exudate. Razenski [39] has shown that in babies sick with what he calls "dyspepsia intestinalis acida lactorum" there is an increased acidity of the intestinal contents and that the utilization of fat is diminished. Meyer and Leopold [40] intimate that a sugar indigestion may cause the appearance of casein curds.

Finkelstein and Meyer [41] believe that milk sugar is the primary cause of the fementative dyspepsias of infancy and that when there is a disturbance of the utilization of fat in these conditions it is a secondary manifestation. They claim that these dyspepsias can be relieved by the long-continued diminution of the carbohydrates in the food and quickly cured by the withdrawal of milk-sugar and the administration of large amounts of casein (*Eiweissmilch*). In general, the fermentation of the sugar depends upon the relation between the casein and the sugar in the food. They advise the administration of other easily assimilable and consequently little fermentable carbohydrates, such as maltose, in place of lactose, after the disappearance of the acute symptoms. Birk [42] and Reuss and Sperk [43] have confirmed their observations. Braumüller [44] calls attention, however, to the danger of the sudden addition of sugar to the diet after it has been withdrawn and large amounts of casein given, believing that under these conditions the ability to form the ferments necessary to take care of sugar is practically abolished.

Kendall [45] has shown that the colon bacillus, like the diphtheria and tetanus bacilli, causes fermentation or putrefaction according to whether it is in a carbohydrate or protein medium, that it attacks the sugar in preference to the protein of the medium and that until the carbohydrate is used up the protein is shielded from attack. The products of the fermentation of carbohydrates are acid. He also showed that the Shiga bacillus produces toxin only when the medium has an alkaline reaction. He, therefore, proposed feeding babies ill with bacillary dysentery with an easily fermentable carbohydrate in order to change the character of the bacterial activity in the alimentary canal from the proteolytic to the fermentative type. The result is to stop further formation of toxin. This was done by feeding the babies a 5% lactose solution, under the influence of which the dysentery bacillus and streptococci tend to disappear.

## Reports of Societies.

### NEW ENGLAND OTOLOGICAL AND LARYNGOLOGICAL SOCIETY.

Meeting, March 28, 1911, Dr. Geo. A. Leland in the chair.

Dr. Edgar M. Holmes read a paper on

A CASE OF VERTIGO CURED BY TREATMENT OF THE EUSTACHIAN TUBE.[1]

DISCUSSION.

Dr. F. P. Emerson: I have been very much interested in what Dr. Holmes reported and I think the direct treatment of the Eustachian tube marks a step forward in the evolution of the treatment of aural disease, and after we have stopped the infection that we all have been treating in the anterior nares, by relieving minor foci, in which there is a discharge of pus directly into the tube, producing some of the conditions which Dr. Holmes has described, the further advance in the treatment of these cases is certainly helped out very much along the line which Dr. Holmes had advocated for it.

I have been very much surprised, in following up a series of cases which had become old chronic office cases, over a long time, in which the symptoms of tinnitus has been markedly relieved by the local application; first using a weak solution of cocaine and adrenaline, and directly following out the lines which Dr. Holmes has followed in this case, and it is surprising how few treatments will relieve the feeling of fullness and dullness in the ears; and the patient will remark that the head feels better, and then the tinnitus is modified. Many cases of tinnitus, which we have thought were located higher up, in the labyrinth or in the middle ear, certainly in my experience have been very markedly relieved by the local treatment, and I think the essential feature in that treatment, in these cases, is the cotton tipped applicator.

Dr. Holmes: There is not much to say. I simply spoke of this one case. I have treated, during the past two months, over two hundred cases. We have kept careful records of them and we have been able to keep tabs on each other by having, most of the time, two and sometimes three on the service, and we have tried not to hypnotize the patients. As Dr. Emerson has said, it is very surprising the relief obtained in these cases, as he said, old cases where they have been catheritized here and there for months, or years, some of them, and they would not come in and say they were very much relieved through any mental thing, I do not believe. We can see in these cases that the inflammation in the tubes is relieved in the same way we can see that we relieve the pharynx by local applications. Of course some of these cases are not relieved; in the middle ear adhesions have taken place which we cannot relieve by any treatment. In regard to these cases, there have been over twenty acute bulging middle ears where we ordinarily would have had to perform paracentesis, and out of those cases all but two, up to date, have been relieved without performing paracentesis; but that will come out in a paper at Atlantic City so I will not go into the details here.

Dr. W. H. Merrill read a paper entitled

A CASE OF NERVE DEAFNESS DUE TO THE TOXEMIA OF DIABETES.[2]

DISCUSSION.

Dr. A. M. Amadon: I am very glad that Dr. Merrill has reported this case, even though he has done it so modestly. It is a case that has interested me though it has embarrassed me to have shot so wide of the mark at the time he kindly allowed me to examine it.

In looking over my notes upon the case I find that the patient said his father was deaf in his old age and that two brothers are deaf. He heard better before getting up in the morning, but the hearing decreased after he was up and about. My hearing test showed some decrease in bone conduction and the upper limits were slightly below normal, but these items were not of great enough moment to convince me that it was a case of labyrinthine deafness. There was moisture in the tube, and by digital examination I found some fibrous bands in Rosenmüller's fossæ which I broke up with my finger. Though the diagnosis was not clear upon the day when I saw the case, I was inclined to consider it a middle ear affection rather than labyrinthine.

In an examination of the literature with Dr. Merrill there was one case of diabetes reported by Dr. Hegener of which the clinical history was given very completely. In that case the amount of sugar was much less than in Dr. Merrill's case. There was a peculiar loss of hearing for sibilants. Some nausea and dizziness were present. The hearing test showed an increasing loss of hearing for the forks as the ascent into the higher tones was made, and the upper limits were reduced. The clinical picture presented by that case strongly suggests the chronic labyrinthine deafness as it is described by Drs. Wittemaak and Manasse, involving degeneration of the nerve fibers primarily and of the structures in the ductus cochlearis secondarily. It is interesting to know that this case recovered hearing with the recovery from the diabetes, but the upper limits of hearing never returned quite to their normal.

There is in Pollitzer's textbook a reference to an early pathological report of a case of diabetes by Steinbrügge in which there were the remains of a slight hemorrhage into the cochlea.

It seems very likely that the pathological condition causing the deafness in these cases is that of the progressive labyrinthine deafness. The absence of dizziness in Dr. Merrill's case would mean that only the cochlear branch of the eighth nerve was affected, while in the case of Dr. Hegener both cochlear and vestibular branches were involved.

## Book Reviews.

*A Textbook of Surgical Anatomy.* By William Francis Campbell, M.D., Brooklyn, N. Y., Professor of Anatomy, Long Island College Hospital; Attending Surgeon to the Methodist Episcopal, Swedish and Bushwick Hospitals; Consulting Surgeon to the Jamaica Hospital. Second edition, revised. With 319 original illustrations. Philadelphia and London: W. B. Saunders Company. 1911.

[1] See Journal, p. 848.

[2] See Journal, p. 849.

This second edition of Campbell's book shows the need and value of the publication and the popularity in which it is held by the profession. We find little to add to our favorable review of the first edition. The work is an accurate, carefully written and important textbook. It should be in every student's library, and will be found a practical and useful book of reference for medical and surgical writers.

*Moto-Sensory Development.* Observations on the First Three Years of a Child. By GEORGE V. N. DEARBORN. Baltimore: Warwick & York, Inc. 1910.

This series of physiologic and psychologic observations on the development of an infant illustrates how easily importance may be attached to what is unimportant and interpretation read into much that is meaningless. The observations are carefully made and minutely recorded, but the love which they indicate seems their chief merit, and the inductions drawn from them do not appear of startling or original value. The entire work, as an "educational psychology monograph," reminds one of the researches of the Laputian academicians.

*Prevention of Infectious Diseases.* By ALVAH H. H. DOTY, M.D. New York and London: D. Appleton & Co. 1911.

This book, representing the results of the author's experience as health officer of the port of New York, deals with the problems of international quarantine prevention of the more serious transmissible diseases, — smallpox, yellow fever, typhus fever, Asiatic cholera and bubonic plague. There are special chapters on classification of the infections, on marine sanitation, on disinfection and disinfectants, on the thermometer, and on the mosquito. The duty of guarding a nation's ports is like that of the individual in guarding the avenues for the entrance of infection into his own body, and can be much more successfully accomplished. One of the great triumphs of modern medicine is to have shown how to prevent the transference of sweeping pestilences from one country to another. Dr. Doty's volume summarizes our present knowledge and methods of this prevention by port sanitation, inspection and quarantine.

*A Manual of Hygiene and Sanitation.* By SENECA EGBERT, A.M., M.D., Professor of Hygiene and Dean of the Medico-Chirurgical College of Philadelphia; Member of the Academy of Natural Sciences of Philadelphia; Member of the American Medical Association, etc., etc. Fifth edition. Illustrated. Pp. 508. Philadelphia and New York: Lea & Febiger. 1910.

In the revision of this well-known, authoritative "Manual of Hygiene and Sanitation" the author not only discusses the fundamental laws of hygiene, but makes clear the advantages which result from action in accordance with such laws. Especially commendable are his efforts to awaken physicians to their need of acquiring a knowledge of hygiene, preventive medicine and sanitary science. We welcome the book as a trustworthy manual of essentials in convenient size, and recommend its use by physicians and by all students of public health and preventive medicine.

*Manual of Diseases of Women.* By W. E. FOTHERGILL, M.A., B.Sc., M.D., Assistant Gynecological Surgeon, Royal Infirmary, and the St. Mary's Hospitals, Manchester; Clinical Lecturer on Obstetrics and Gynecology in the Victoria University of Manchester. With 144 illustrations in the text. New York: William Wood & Co. 1910.

This is an excellent small book of four hundred and thirty-three pages written in a readable colloquial style which brings into prominence the important features of the pathology, symptomatology, diagnosis and treatment of pelvic diseases.

The illustrations, most of them original, are satisfactory from the standpoint of making plainer the text rather than being crowded in in great profusion because the author or the publishers wished to make a display, as happens so frequently in the textbooks of the present day.

The paper and the press work are good. The book is light in weight and of such size that it will slip into a large coat pocket.

Aside from a few essential points of technic such as, "the examination is most satisfactorily made if the patient is in bed," with which it is hard to agree, the book can be recommended heartily to the practitioner of medicine.

*The History of Medicine, Philosophical and Critical, from its Origin to the Twentieth Century.* By DAVID ALLYN GORTON, M.D. In two volumes. New York: G. P. Putnam's Sons. 1910.

The author in these two volumes, together comprising somewhat less than a thousand pages of text, has undertaken a large task in discussing the history of medicine from the earliest years to the twentieth century. The result has been very naturally a cursory description of many important periods, but this necessary superficiality is more than compensated by the readability of the text and the comprehensive survey which brevity permits of the entire history of medicine up to very recent times. The author has discussed theories and ventured opinions which add rather than detract from the merit of the book as a whole. The apologetic attitude assumed in the preface is certainly unnecessary, although few will agree with certain of the radical opinions expressed. The volumes are admirably printed, sufficiently illustrated, largely by more or less familiar cuts of the distinguished men of various periods. A very complete index adds materially to the value of the book, which we are glad to recommend to the attention of students of medical history and others interested in the somewhat erratic development of a great profession.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, JUNE 15, 1911

*A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.*

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

*All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston.*

*All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.*

*Remittance should be made by money order, draft or registered letter payable to*

W. M. LEONARD,
101 Tremont Street, Boston, Mass.

## SIR JAMES YOUNG SIMPSON.

On June 7, 1811, was born James Young Simpson, destined later to be the first demonstrator of surgical anesthesia by means of chloroform and to become one of the eminent figures in the history of medical science. The centennial anniversary of his birth is an appropriate occasion for reviewing some of the details of his life and of the work which he accomplished.

James Young Simpson was born, a seventh son, in the little village of Bathgate, Linlithgowshire, Scotland, of poor but thrifty parents. He was early selected as the member of the family to receive an education, and after ten years of common schooling entered Edinburgh University at the age of fourteen. Here he speedily justified the confidence that had been placed in his promise: he worked hard, slept little, and took high rank in all his studies. He had a catholic and devouring taste for knowledge, but was particularly devoted to inquiry in the physical sciences. It was natural that he should determine on medicine as his profession, and in 1835 he was established in its practice at Edinburgh. Already he had accomplished valuable work in microscopic pathology, but his instincts were temperamentally clinical, and it was in obstetrics that he found the most congenial field for the exercise of his peculiar talent. In 1836 he published his first and still famous monograph on "Diseases of the Placenta." So rapidly did his reputation increase as a practitioner and teacher that on the death of Hamilton, in 1840, he was appointed the latter's successor as professor of midwifery at the University of Edinburgh, — at the age of twenty-nine! In this office and in his practice he continued with the same active and unremitting energy. He made many contributions to the progress of his speciality, among them the invention of the cranioclast, and found time as well for investigations in other branches of medicine, and in archeology, his avocation. He was honored with an appointment as physician to the Queen, and at the age of thirty-five had reached a position of national reputation.

It was at this juncture, in 1846, that the report came from Boston of Morton's demonstration of surgical anesthesia by sulphuric ether. Simpson was one of the earliest in Great Britain to appreciate the full meaning of this great discovery, and was the first to employ ether in obstetrics, using it successfully in a case in which he performed version for contracted pelvis. The new agent, however, was disagreeable and irritating, and he immediately set about the search for other anesthetic substances of equal efficacy and without these disadvantages. Like Morton and Hunter and other great scientific zealots, he experimented upon himself, inhaling various volatile fluids, such as acetone and benzine, and noting their effects. His method was as empiric and rational as that of Ehrlich in the discovery of salvarsan. Finally, on Nov. 4, 1847, he essayed chloroform. At first he "became bright-eyed, very happy, and very loquacious." Then he heard sounds "like those of a cotton-mill, louder and louder; a moment more, then all was quiet, and then a crash!" He woke to find himself on the floor, whence he had fallen from his chair. With him were his assistants, Dr. Duncan and Dr. Keith, who also had partaken of the "potent poison." They and others in the household repeated the experiment many times that night, sitting up till three the next morning.

On Nov. 10, 1847, Simpson formally communicated to the Medico-Chirurgical Society his discovery of the anesthetic properties of chloroform. A few days later he first employed it successfully in a case of labor; and from that time its use became general throughout Great Britain. His fame was now international, yet his professional zeal was not in the least abated thereby, but continued undiminished to the end. In obstetrics he was particularly urgent in his advocacy of the value of version as a means of avoiding craniotomy. In the newer field of gynecology he was a pioneer, and his many papers and lectures on that subject remain classics to this day. Particularly does he deserve credit for the clearness with which he saw and the insistence with which he taught that obstetrics and gynecology inseparably constitute a single

department of medicine. He of course knew nothing of bacteriology and asepsis, and to him therefore the great later domain of major surgery was closed, though he was one of the early ovariotomists. He was of those whose labors and observations paved the way for the brilliant progress of surgery during the past forty years.

In 1886 Simpson was created a baronet, and on May 6, 1870, he died full of honors and keen with energy to the last. The centennial of his birth has been the occasion of many observances in Great Britain. He is well remembered in his native land. At Edinburgh his monument stands in Prince's Street with those of Scotland's greatest sons. The current issue of the *Edinburgh Medical Journal*, published as a *Festschrift* in his memory, is devoted to numerous interesting articles descriptive of his life and work. He will always be most famous for his demonstration of chloroform, which, despite its now appreciated risks, remains one of the standard and beneficent anesthetic agents of medicine. He deserves credit and reputation none the less, however, for his contributions to the teaching and practice of obstetrics and gynecology, and for his early efforts to demonstrate their unity. His personal character, his professional zeal, the brilliancy of his scientific attainments all merit the highest admiration. His name will remain one of the greatest that Scotland has given to the history of medical and of human progress.

## SOME POSSIBLY FRUITLESS MODES OF SOCIAL ENDEAVOR.

IN last week's issue of the JOURNAL we gave some preliminary notice of the National Conference of Charities and Correction, then in session in Boston. The meetings of the various sections of this convention have continued through the week, the entire gamut of sociologic problems has been discussed, from juvenile delinquents to recreant husbands, with "great argument about it and about." And now that the conference is at an end, the question arises of its actual accomplishment. Doubtless the discussion of vexing problems is profitable, even if no dicision be reached. Doubtless, too, a vast amount of good is accomplished by such organized charities throughout the land. There always remains the query, however, whether some of the activities of the charitable and social-service worker may not at times be supererogatory and meddlesome.

In the issue of *Science* for June 2 is an article by Professor Edwin O. Jordan, on "Profitable and Fruitless Lines of Endeavor in Public Health Work." It is characteristic of human frailty, having hit upon an advantageous mode of activity, immediately to overdo the same with a great consciousness of rectitude. A deal of energy is developed, like that of a squirrel turning round in a revolving cage, but there is no tangible or profitable result. Excess of zeal in action is mistaken for actual accomplishment. So, Professor Jordan points out, "a part of the energy of almost every municipal health department is devoted to combating imaginary dangers, or applied to tasks that have only a remote bearing on the public health." This is strong language to which we are not inclined to give unqualified assent, but it suggests at least a definite point of view. Garbage disposal and plumbing inspection are examples of activities in which much energy is wasted since, "Sanitarians do not admit that even a grossly improper method of garbage disposal can have much to do with the spread of disease in a sewered city."

Yet these activities often usurp much of the time and money of municipal health departments.

Similarly in the field of social service there are or may be fallacies pursued with zeal because their validity is accepted without criticism. For instance, to what end should the intemperate husband be driven from the saloon to the cocaine den, when it was the disappointment of the utterly selfish and useless wife that first sent him to the saloon? Or to what end should bath-tubs and recreation grounds be freely provided for those who use the former to store household miscellanies and who scatter all manner of scraps on the latter? The parable of casting pearls has not yet wholly lost its applicability, and it was spoken by one dedicated to the social service of mankind.

These comments are made purely in the line of suggestion, not at all in the spirit of unkindly criticism. They are merely intended to point out some of the possibilities of fruitless endeavor on the part of those whose laudable motives and precious energy might be profitably applied. It is as profitless as pouring water in a sieve to labor unduly in the effort to reclaim the unfit, when the conditions that make their unfitness are rooted in the fiber of their own composition. It is profitless to expend great toil in removing a few grains of sand, when it is the tides of an eternal sea that from day to day are shaping the shore. Natural process in the evolution of man

had begun when the first ameba failed to reach the morsel of food that was grasped by the pseudopodium of his more able brother, and it will continue to regulate man's destiny on earth without appreciable modification until the end.

## SANITARY CONDITIONS OF MASSACHUSETTS FOUNDRIES.

THE monthly bulletin of the Massachusetts State Board of Health for April contains an interesting paper by Dr. William C. Hanson, assistant to the secretary of the Board, on "Sanitary Conditions in Foundries in Massachusetts." During the year 1910, 209 foundries were inspected in this State, of which 163 employed ten or more workers each, and 46 employed less than ten. In these foundries are carried on numerous different processes, the hygienic importance of which is that "they expose the workmen to extremes of temperature, to dust, and to more or less irritating gases and vapors."

One of the subjects particularly investigated was the occurrence of so-called "foundry chills," which apparently represent an acute intoxication from inhaling the fumes generated in smelting zinc and other ores.

"In foundries where brass or composition is cast, employees are exposed to fumes from the zinc which enters into the composition of these metals. The metals are usually melted in firepots which are most frequently below the floor. These are covered with iron covers so that during the melting few or no gases escape. In the foundries where the metal was melted the blast furnaces were found properly hooded to carry off the fumes. When the metal is ready for pouring the crucibles are lifted out by means of long iron holders and are carried by two men to the moulds where it is poured. It is during this process that the zinc volatilizes and is given off as dense gray fumes, which, on being cooled by the air of the room, precipitate into fine gray powdered flakes which fill the room, and are unavoidably inhaled by the workers. Brass casters, as well as men who cast composition containing a high per cent of zinc, frequently suffer from what is known as 'brass chills.' Those are more apt to suffer who are not used to this kind of work or who return to it after an intervening period during which such work was not done. The 'chills' are apt to occur on damp, cloudy days, when the fumes, generated during casting, are not readily carried out of the foundry. The 'chills' usually come on in the late afternoon or on reaching home in the evening The worker experiences an irritation of the throat, a metallic taste in the mouth, and pains all over his body, as if suffering from an attack of 'la grippe.' Shortly after the 'chills' set in they occur intermittently for a few hours and then terminate in a profuse sweat. Most often the worker feels well enough in the morning to return to work. Occasionally, however, a man may have to stay out of work for a day or two."

Besides these cases of acute zinc poisoning, other forms of metallic poisoning were observed, notably one case of chronic lead poisoning and one of chronic antimony poisoning.

The foundries were further inspected with a view to the means afforded to employees for protection from dust, for cleanliness, for light, and for ventilation. In general the conditions were found to be fairly good, but 106 orders were issued relative to various defects observed. The conclusion of the paper is that much education is still needed among both employers and employed, to make the former realize that good sanitary conditions are an asset because they increase the efficiency of the worker, and to teach the latter to recognize the dangers to which he is exposed and to utilize the facilities which are afforded for his protection.

## THE NEW MEDICAL BUILDING OF McGILL UNIVERSITY.

THE formal opening of the new medical building of McGill University was celebrated with appropriate ceremony at Montreal, on Monday, June 5. At three o'clock in the afternoon was held the annual convocation for conferring degrees in medicine and agriculture, at which were present many graduates of the university, and representatives from medical schools in other parts of Canada, in England, in Scotland, and in the United States. The honorary degree of LL.D. was conferred on several of the distinguished guests, among them Dr. Lewellys Franklin Barker, professor of medicine at Johns Hopkins University, Baltimore, Dr. William Thomas Councilman, professor of pathology at the Harvard Medical School, and Dr. John Collins Warren, F.R.C.S. (Eng.), of Boston.

At nine o'clock in the evening the new buiding was officially opened by his Excellency, Earl Grey, Governor-General of Canada and visitor of the University. This ceremony was followed by a concert and dance. The new building, which is the largest of the university group, is built of limestone and is of modern fireproof steel construction throughout. It contains well-equipped laboratories, a museum, and abundant provision for class rooms and lectures. In architectural appearance it is charmingly suggestive of some of the older university buildings in

England and Ireland. Its erection and equipment, at a cost of nearly $800,000, have been made possible largely by the munificent generosity of Lord Strathcona, a frequent former benefactor and patron of McGill University.

On Tuesday, June 6, was laid by Earl Grey, the cornerstone of the new building of the Montreal General Hospital, an institution whose history has been closely associated with that of the medical school. Following this ceremony was a garden party, and in the evening a dinner given by the dean, professors, and members of the teaching staff of the faculty of medicine of the McGill University. In connection with the celebration of these two days was held a reunion of the graduates in medicine of the university.

These events mark an important step in the progress of medical education not only in Canada, but upon this continent, for they signalize the endowment with adequate facilities for efficient work of another of the great medical schools of America.

## CENTENNIAL OF THE RHODE ISLAND MEDICAL SOCIETY.

THE one hundredth anniversary of the Rhode Island Medical Society was celebrated at a meeting held on June 1, at Providence, R. I. After presentation of the annual reports and election of officers for the ensuing year, Dr. G. Alder Blumer delivered the address of the occasion, entitled "A Plea for the Medical Library," describing the steps in the development of the library of the society and the efforts that have recently culminated in the raising of a sum sufficient to begin the erection of a new and separate building for its accommodation. This library of over thirty thousand volumes, one of the large and important collections of medical literature in this country, has hitherto been stored in the Rhode Island Public Library building. The provision of suitable quarters for the care and use of this medical library has been one of the earnest desires of the Rhode Island Medical Society, and the ceremony of laying the cornerstone of the new building appropriately marked the centennial anniversary of its organization.

The cornerstone was laid by Dr. Frank L. Day, who further described the stages in the growth of the library and the importance of such an institution, not only to medical education, but to the public welfare. Addresses were also made by the Governor of Rhode Island, by the Mayor of Providence, and by Dr. Frederick C. Shattuck, of Boston. At the annual dinner, which was attended by about two hundred and twenty-five physicians, there were addresses by Dr. Arthur Hollingsworth, the anniversary chairman, and by Dr. Hugh Cabot, of Boston.

A full account of the proceedings on this interesting occasion will be published in a later issue of the JOURNAL. The Rhode Island Medical Society is one of the older state medical organizations in this country, and the conclusion of its first century of honorable service in the community is a source of pleasure and satisfaction to members of the profession throughout the United States.

## TESTIMONIAL TO DR. OWEN COPP.

IN recognition of Dr. Owen Copp's long service to the Commonwealth as executive officer of its Board of Insanity, and in view of his forthcoming departure to accept the position of superintendent of the Pennsylvania Hospital for the Insane, a dinner was given him on June 9, at the Union Club in Boston. Some forty men were present to testify to their regard for the eminent services rendered by Dr. Copp to the cause of insanity in this state. Dr. Walter Channing presided, and with appropriate introductions, called upon a number of men closely associated with the work of psychiatry, who spoke feelingly with reference to Dr. Copp's share in the development of our system of caring for the insane. The speakers were Dr. Edward Cowles, Dr. William N. Bullard, Mr. William F. Whittemore, of the State Board of Insanity, Dr. Herbert B. Howard; Dr. George T. Tuttle; Dr. Walter E. Fernald, and Dr. G. Alder Blumer, of the Butler Hospital. All of these speakers in their varying ways and from their personal points of view showed wherein Dr. Copp had proved so useful a public servant, and so widely influential in developing a policy which may well stand as a model for the treatment of the insane in other states, as well as a means of further investigation in the difficult field of mental disease. Dr. Copp when called upon to speak, showed much appreciation of what had been said of him; but with becoming and characteristic modesty disclaimed the justice of so high a degree of praise. His remarks were also noteworthy in that he succinctly summarized his views regarding the relations of the governing boards of institutions, and clearly pointed out wherein the sources of inefficiency lay in the various methods of control. A fitting close to the dinner, which will be remembered by all those

present as a memorable testimonial to exceptional efficiency, was the presentation to Dr. Copp by Dr. Henry R. Stedman of a handsome loving cup bearing the following inscription: Presented to Dr. Owen Copp by a number of friends in recognition of his distinguished service to the insane of Massachusetts, June 9, 1911. The cup was accepted with grace and deep feeling.

## MEDICAL NOTES.

Yellow Fever at Kingston. — A press report from Kingston, Jamaica, states that a case of yellow fever was discovered in that port on June 6.

Case of Cholera at Berlin. — A press despatch from Berlin states that on June 5 a case of Asiatic cholera was reported in that city.

Baltimore College of Physicians and Surgeons. — The Tri-State Chapter of the graduates of the College of Physicians and Surgeons, of Baltimore, has been organized to include the graduates of that college residing in New York, New Jersey and Connecticut.

London Death-Rates in April. — Statistics recently published show that the death-rate in London for April, 1911, was 15.5 per 1,000 living. Among the several districts and boroughs, the highest rate was 20.8 in Shoreditch, at the east end, and the lowest 10.4 in Lewisham, a southern suburb.

Cholera Aboard the Saxonia. — It is reported in the daily press that on June 5 the steamship *Saxonia* was detained in quarantine at Trieste, Austria, on suspicion that a death which occurred in the steerage during the voyage from New York was due to Asiatic cholera. Bacteriologic examination is being made of the stools of several passengers who have had recent enteric disturbances and are suspected of being possible cholera carriers.

Vital Statistics of Montclair, N. J. — The recently published sixteenth annual report of the board of health of the town of Montclair, N. J. describes the operations of the Board during the calendar year 1910, and records the vital statistics for that period. The death-rate of the town in 1910 was 11.12 per 1,000 of population, the birth-rate 19.4 and the marriage-rate 7.3. Of the total number of deaths, 16.1% were recorded as due to tuberculosis, and 14.5 due to pneumonia. There was a marked increase during this year in the prevalence of certain communicable diseases, especially scarlet fever and diphtheria. On the whole, however, the hygienic and sanitary conditions of the town have been excellent, and it is to be noted that there was not a single death from typhoid fever during the year.

English and Welsh Vital Statistics for 1910. — Completed vital statistics of England and Wales for the year 1910, issued in London on June 10, indicate a slight increase in the number of marriages in these two countries and a decrease in both births and deaths. In 1910 there were 267,000 marriages, corresponding to a rate of 14.8 persons per 1,000 of the population of all ages. In 1909 this rate was only 14.6, but in 1899 it was 16.5, and in the decade from 1900 to 1909 it was 15.5. The number of deaths in 1910 was 483,000, a rate of 13.4 per 1,000, as against 14.5 per 1,000 in 1909, the lowest figure previously recorded.

"The proportion of deaths under one year of age to registered births was 106 per 1,000 in 1910, or 3 per 1,000 less than 1909, the lowest recorded up to that year. Compared with the decade 1900–1909, the rate of infantile mortality showed the remarkable decrease of 26 per 1,000 births. Births numbered 897,000, an average of 24.8 per 1,000 of the population at all ages. This was 0.8 per 1,000 below the rate in 1909, which was the lowest rate reached till then. Compared with the preceding ten years, the birth-rate showed a decline of 2.7 per 1,000.

With regard to London, the marriages in 1910 numbered 39,000, a rate of 16.0 per 1,000 of all ages, or an increase of 0.2 per 1,000 on the previous year. The London births numbered 114,900, a proportion of 23.6 per 1,000 of the total population — the lowest in the Metropolis since civil registration was established. Deaths in London were 61,700, a rate of 12.7 per 1,000 of the population. This was 1.3 below that of 1909, which was at that time the lowest on record."

### BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, June 6, 1911, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 85, scarlatina 26, typhoid fever 9, measles 156, smallpox 0, tuberculosis 76.

The death-rate of the reported deaths for the week ending June 6, 1911, was 15.97.

Boston Mortality Statistics. — The total number of deaths reported to the Board of Health for the week ending Saturday, noon, June 10, 1911, was 178, against 206 the corresponding week of last year, showing a decrease of 28 deaths, and making the death-rate for the week,

13.47. Of this number 96 were males and 82 were females; 171 were white and 7 colored; 101 were born in the United States, 73 in foreign countries and 4 unknown; 41 were of American parentage, 112 of foreign parentage and 25 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 84 cases and 0 deaths; scarlatina, 22 cases and 1 deaths; typhoid fever, 10 cases and 1 death; measles, 147 cases and 2 deaths; tuberculosis, 65 cases and 17 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 15, whooping cough 1, heart disease 25, bronchitis 1. There were 7 deaths from violent causes. The number of children who died under one year was 26; the number under five years, 39. The number of persons who died over sixty years of age was 61. The deaths in hospitals and public institutions were 76.

BIRTH OF TRIPLETS IN QUINCY. — Report from Quincy, Mass., states that on June 10, Mrs. Myer Winer, of that city, gave birth to triplets, two boys weighing five pounds each and a girl weighing four and one-half pounds. The girl and one of the boys died after a few hours.

GRADUATION OF NURSES AT LONG ISLAND HOSPITAL. — At the graduation exercises of the Long Island Hospital Training School for Nurses, held last week, diplomas were awarded to thirteen pupils of the institution. Addresses were made by Dr. Laura Hughes, and by Dr. Theodore J. Eastman, of Boston.

FINES FOR ILLEGAL TRAFFIC IN COCAINE. — Before the Boston municipal court last week a dealer in this city was fined a total of $135 on four counts: For having cocaine in his possession; for being present where cocaine was sold; for selling cocaine; and for assault and battery on the agent who detected the sale. Two of his associates, one from Boston and one from Providence, R. I., were also fined $25 each for being present where cocaine was found.

EXHIBIT OF ASSOCIATION FOR CONSERVATION OF VISION. — There is at present on view at 5 Park Street, Boston, an exhibit of the American Association for the Conservation of Vision, intended to illustrate the ways in which eyesight may be injured or impaired and to instruct the public in the proper use of the eyes. This exhibit, which was orginally prepared for the International Blind Workers' Exposition, in New York, has lately been shown at the Child Hygiene Exhibit, recently held in Chicago.

RELATION OF STATE BOARD OF HEALTH TO HOSPITALS FOR CONSUMPTIVES. — In the Massachusetts State Senate, on June 5, the committee on public charitable institutions reported favorably "a bill providing that instead of the State Board of Charity, the State Board of Health shall receive written reports of the trustees of hospitals for consumptives at the end of each quarter, and that the State Board of Health shall appoint an executive secretary to the trustees of hospitals for consumptives at a salary of $5,000, who shall at all times be under the supervision and control by the State Board of Health. The bill is based on the petition of Edward F. McSweeney."

REPORT OF THE DEACONESS HOSPITAL. — The recently published annual report of the Deaconess Hospital, Boston, presents the record of work of this institution for the calendar year 1910. During this year 1,051 patients were received into the Hospital, and 7,639 calls were made by the district nurses. Ten nurses were graduated from the training-school. Attention is called to the need of enlarging the hospital building and of establishing a nurses' home. For these purposes the sum of $100,000 is required. The report contains a description and attractive picture of the Deaconess Hosiptal now in process of erection at Concord, Mass., to which reference has been made in previous issues of the JOURNAL.

REPORT OF THE SCHOOL FOR FEEBLE-MINDED. — The sixty-third annual report of the trustees of the Massachusetts School for the Feeble-Minded, at Waltham, Mass., describes the work of this institution for the year ending Nov. 30, 1910. The number of inmates at the close of that year was 1,430, of whom 1,200 were at Waverley, Mass., and 230 at Templeton, Mass. The steady increase in numbers makes the present accomodations already inadequate. This year an entirely new hospital for adult males is requested, and in the near future some provision must be made for a colony for the segregation of the criminal defectives. The report of the superintendent, Dr. Walter E. Fernald, tabulates the statistics, and elaborates the details of work of the school. There is appended an excellent monograph on classification and method of training and instruction.

BEQUESTS TO MEDICAL CHARITIES. — An attested copy of the will of the late Miss Marion R. Lord, of Wells, Me., who died on Jan. 5, 1910, was filed last week before the Suffolk Probate

Court, Boston. Among numerous bequests to local charitable institutions, it contains one of $2,000 to the Industrial School for Crippled and Deformed Children, and two of $1,000 each to the Boston Floating Hospital and the Newton (Mass.) Hospital.

The will of the late Joseph Descalzo, of Cambridge, Mass., who died on June 5, was filed last week at the East Cambridge Probate Court. It contains a bequest of $1,500 to the Children's Hospital, Boston, and one of $1,000 to the Perkins Institute for the Blind, Boston.

The will of the late Arthur J. C. Sowdon, of Boston, which was filed on June 6, in the Suffolk Registry of Probate, contains a bequest of $1,000 to the Industrial School for Crippled and Deformed Children, "as a thank offering for partial recovery from severe illness."

Two Living Centenarians. — In the issue of the Journal for June 16, 1910, we noted, with pleasure, the longevity and persistent good health of Mrs. Lavinia Parks, of Russell, Mass., who is locally reputed to have been born on June 6, 1809, at Blandford, Mass. Mrs. Parks has for another year survived the vicissitudes of life, and celebrated last week the supposed one hundred and second anniversary of her birth. She is said to be still in excellent bodily and mental health, though her hearing and eyesight are beginning to fail.

Mrs. Susan E. Locke, of Lynn, Mass., celebrated last week the supposed centennial anniversary of her birth, by driving in a motor car to Bass Point, Nahant. She is said to have been born in 1811, at Burlington, Vt., the oldest of a family of twelve children. After her marriage she lived for a time in Wilmington, Mass., but for the past thirty years has been a resident of Lynn. She is said to exhibit a remarkable degree of physical and intellectual vigor and alertness. She has three living daughters, (two of whom are twins), fourteen grandchildren, nine great-grandchildren and five great-great-grandchildren.

Hours of Work for Nurses. — In last week's issue of the Journal we published an editorial on "Hours of Work for Nurses." In this connection the following letter, printed in a Boston daily paper, on June 5, seems pertinent and deserving of republication.

"I have noted remarks of Mayor Fitzgerald and others on 'Nurses' Hours,' in Boston hospitals. Can I trespass on your space and call attention to the way it struck me from what I saw at the Massachusetts General, as a patient. Nurses came on duty at 7 A.M., after having had their breakfast, had time at noon for lunch and time for supper before going off duty at 7 P.M. Other time off daily was at least one hour and sometimes four (Sundays and holidays) and lectures occurred frequently; at such times they went off duty at the ward they were attached to. Actual time on duty approached eight hours nearer than twelve. After graduating at the end of three years' service, nurses get $21 a week or better and their board, and good nurses are employed a good portion of their time. A girl has to be fitted by nature to become a good nurse. Their time is not their own, but in what profession can a young woman get better pay? Hospitals take lots of money to run. If a nurse could be employed by law only eight hours a day, could the hospitals do as much with the means at their command as they do and could the nurses get the experience they do in the same time?

"Is there any school that will board a pupil, give the scholar the training the City or Massachusetts General Hospitals do and pay them something toward their clothing?"

An Ex-Patient.

Reorganization of Massachusetts Infant Asylum. — The board of directors of the Massachusetts Infant Asylum, after recent careful study of the affairs of the institution, has issued a plan for its reorganization.

"An investigation of the field of infant charities in Boston, with the view to ascertaining whether there exists any unnecessary duplication of service, has shown that at the present time there are not enough hospital beds for infants. It would, therefore, be a serious loss to the community if the work of this institution should be impaired in its vigor or efficiency.

"Without criticising the managment in the past, the Board is convinced that present conditions require certain marked and important changes in administration, which are in direct line with the progressive idea of bringing similar medical-social institutions into close relations with each other. To afford the best opportunities for the study of infants' diseases and proper facilities for teaching, it is essential that the medical schools should serve as the scientific centers for the different groups of institutions, of which the infant charities perhaps form the most important group of all. In accordance with this general plan it was decided that it was wise to change the system of medical service of the Massachusetts Infant Asylum, to provide that a physician-in-charge, who is a recognized specialist in infants' diseases and who is directly connected with the Harvard Medical School, shall be given a continuous service, and be held responsible for the medical administration of the hospital, with such assistants as he may select, to be appointed by the Board. Dr. Henry I. Bowditch has been appointed physician-in-charge. by the board of directors, having been nominated by the Corporation of Harvard University."

Dr. Arthur I. Kendall, of Somerville, Mass., instructor in preventive medicine and hygiene in the Harvard Medical School, has also been appointed to have charge of the bacteriologic and other laboratory work of the asylum.

"In making the changes outlined above, the board of directors wishes to express its appreciation of the long and devoted services of the members of the retiring medical staff, who have resigned in order that the new system may go into effect."

In connection with this reorganization arises the question of the desirability of changing the name of the asylum.

"The advisability of changing the name of the institution has been under consideration for a long time, and the Board feels very strongly that it should be done as soon as possible, with the general consent of the Corporation. The word 'asylum' is associated in the popular mind with much that is unpleasant in the past, and for this reason alone it is being rapidly discarded. Moreover, it no longer adequately or correctly describes our work, which is essentially that of a modern hospital with an effective social-service department. Of the various names which have been suggested, the most desirable one seems to be the Massachusetts Infant Hospital, which necessitates the change of only one word."

The reorganization and proposed extension of the work of this institution make necessary a larger annual income to provide for its running expenses. The directors, therefore, make appeal to the public for subscriptions to the amount of $12,000 each year for this purpose. For forty-four years the Massachusetts Infant Asylum has rendered to this community admirable service in both remedial and preventive work; and at this time, when it is planning a larger scope and greater opportunity of future service, its needs should not be unheeded by generous friends of medical charity.

## NEW YORK.

DIRECTOR OF PHŒNIX RESEARCH LABORATORIES. — At a meeting of the trustees of Columbia University, held on June 5, Prof. M. I. Pupin was appointed director of the Phœnix Research Laboratories. Among the gifts announced was $33,133 from the committee appointed to raise the William T. Bull memorial fund.

COMMENCEMENT OF NEW YORK UNIVERSITY. — At the seventy-ninth annual commencement of New York University, on June 7, the degree of Doctor of Medicine was conferred on 68 graduates and that of Doctor of Veterinary Surgery on 6. E. Hausmann received the degree of Doctor of Science and C. F. Longfellow that of Bachelor of Science in Medicine. In the medical school the Glover C. Arnold surgical prize was awarded to Isadore S. Faust, and the three Valentine Mott medals for anatomical preparations to Isidor Elau, Luigi Celano and Alexander Aisman.

COMMENCEMENT AT COLUMBIA UNIVERSITY. — At the one hundred and fifty-seventh annual commencement of Columbia University, on June 7, the degree of Doctor of Medicine was conferred on 69 graduates, that of Doctor of Pharmacy on 3, and that of Pharmaceutical Chemist on 11. Among those who received the honorary degree of Doctor of Laws was Dr. Charles F. Chandler, Mitchell Professor of Chemistry at Columbia. The degree of Doctor of Science was conferred on Dr. Charles Francis Stokes, College of Physicians, 1884, now Surgeon-General of the United States Navy.

CONFERENCE OF NATIONAL HOUSING ASSOCIATION. — The National Conference of the National Housing Association, was held in New York on June 5 and 6. Numerous papers were presented. The sessions were at the Charities Building, on Fourth Avenue, and visits were made to congested districts of the city under the direction of inspectors of the Tenement-House Department. One point appears to have come prominently to the front at the conference. The tenement is regarded by all who have investigated it scientifically as a habitation to be excused for existing only on the score of necessity. The visiting experts saw what New York has done to improve its tenements, not only by legislation, but by private effort; yet every allusion to the erection of similar buildings in other cities was always made with an expression of regret. On the other hand, Miss Helen Parrish, of Philadelphia, and J. H. Hanson, of Youngstown, Ohio, presented the results of actual experience of other communities in the provision of small but comfortable and sanitary dwellings for families who can afford only from $10 to $20 a month; showing that there was really nothing charitable about their erection, as they had proved to be a good business investment. The necessity for the proper supervision of housing in the smaller cities, as well as the larger ones, was brought out by Elmer S. Forbes, chairman of the State Housing Committee of the Massachusetts Civic League. In the towns with a population of from 2,500 to 25,000, he said,

there might be discovered, if not slum districts, at least slum spots, which might easily spread. He thought the community should be enlightened as to the danger from these, and recommended the adoption by the smaller towns of a simple tenement-house law adapted to their conditions. Luther E. Lovejoy, secretary of the Housing Commission of Detroit, presented a paper in which special stress was laid on the fecundity of the house-fly. "Between Spring and Fall," he declared, "two industrious flies can become the proud progenitors of at least nineteen quintillions (19,000,000,000,000,000,000) of lusty maggots." This brought up the subject of the disposal of garbage in cities, and Virgil G. Marani, of Cleveland, advocated the use of paper garbage receptacles, which might be removed and destroyed with the waste. These, he said, would cost very little, and then there would be no more dirty cans, from which it was practicably impossible to remove every trace of garbage.

6. Gulliver, F. D. *Mental Suggestion as a Substitute for Anesthetics in the Removal of Tonsils and Adenoids from Children.*

4. Roberts makes some interesting observations on belching. Gas in the stomach, he says, is rarely anything but swallowed air, as true fermentation takes place in the stomach only as a result of actual stasis. Slight eructation of gas after a full meal has no pathological significance. Belching is a voluntary act performed in an exaggerated manner to relieve real or fancied epigastric distress. The most exaggerated form of belching results from emotional states. Gas is complained of in certain abdominal conditions by patients who do not belch. This is especially common in the discomforts associated with disease of the biliary tract, appendix and colon. The distress in these cases is not due to gas at all. [L. D. C.]

6. McGlinn made a post-mortem study of 113 cases of uterine myomata in order to determine the relation which these tumors bear to chronic heart disease. He concludes that a definite entity of a fibroid heart cannot be sustained. Uterine myomata occurring during middle and advanced life are practically always associated with sclerotic heart lesions, but these are a part of a general process and are not related to the fibroid. Many of the cardiovascular symptoms in myoma cases are due to secondary anemia *per se*. [L. D. C.]

2. Brem states that tuberculosis is the most common of all diseases and causes a greater number of deaths than any other. Failure to diagnose it early is disastrous and reprehensible. There is no disease in which neurasthenia is as common as in tuberculosis. It is often one of the early symptoms. Physicians should have a more thorough knowledge of tuberculosis than of any other disease and should be trained to the highest degree in methods for diagnosing it in its early stage. The greatest hope for the ultimate control of tuberculosis lies in the education of the physician in early diagnosis.

3. Bell says that the profession is not educated to a proper attitude toward the early diagnosis of pulmonary tuberculosis, that it does not train itself minutely enough in the early signs and does not avail itself of the valuable corroborative tests which science has placed at our disposal.

9. McDonald claims that in subacute otitis media no other means of treatment is capable of producing such uniformly good results as vaccines. Their early use should greatly diminish the number of chronic cases so common. Results in chronic cases are, however, more variable. The use of vaccines as a routine should not be advised in chronic cases, but should be tried when other measures fail.

11. Davis does not advocate rectal puncture in all cases of large appendix abscesses, but he believes that there are certain definite, though narrow, indications for this procedure. The type is that of the late or neglected case, when there is profound sepsis and exhaustion and a large mass to be felt bimanually and bulging into the rectum. In such cases puncture is easy and generally followed by great immediate relief, and may often tide the patient over till his condition warrants further operative procedure.

5. Roubitschek has tried out the use of hydrogen peroxide in cases of hyperacidity of the stomach. He finds the fluid preparations more satisfactory than the solid combinations. He first advocates internally ½% solution, 300 ccm., three times a day. If this does not work he advocates a ¾% or 1% solution. One per cent solution may cause vomiting and stronger solutions are quite apt to. After a few days' use the pain will disappear and will not return again. He advocates also restrictions in diet.

7. By a series of tracings from different parts of the mother Reifferschied has demonstrated what he feels sure are respiratory fetal movements. He rules out these movements as being uterine because they are only obtained when the tambour is over that part of the uterus where the child touches. They are not synchronous with any other movements of mother or child.

1. v. Pirquet gives the results of a series of tests with cowpox vaccine along the lines of earlier work with serum sickness. He finds a striking similarity of results and summarizes as follows: (1) As in serum sickness, so also after injection of cowpox vaccine, two forms of allergy may occur; namely, the immediate and the accelerated reaction. (2) The accelerated reaction follows either the cutaneous use of active lymph or the subcutaneous injection of killed lymph. (3) The "double reaction," as in serum sickness, may occur, i. e., successive appearance of immediate and of accelerated reaction.

2. Assuming the value of high altitudes for certain conditions, the writers evolved the thesis that the beneficial effects result from diminution of oxygen, and that the dangers are due to low atmospheric pressure. They then constructed an apparatus to administer air with diminished oxygen at existing pressure. Animal experiments showed that a reduction of the oxygen to 12–14% caused intense hyperemia of the lungs. The treatment was then tried on twenty patients, most of whom had chronic bronchitis or anemia of some sort, and the results were encouraging.

3. Emmerich brings forward new evidence in favor of the theory that the primary poison in cholera is nitrous acid. (This question deserves careful investigation by those having the opportunity to study cholera or allied diseases.)

Nitrous acid was found in considerable amounts in the vomitus, in the urine and in juice squeezed from the wall of the small intestine in a number of cases, but not in the blood. The writer asserts that this finding is pathognomonic for cholera and closely allied conditions.

1. Having studied 140 cases of tuberculosis, the writers demonstrated orthotic albuminuria in a surprisingly large proportion. None of the cases were febrile and none were bedridden. In the early cases albuminuria was demonstrated in a very large proportion after the patient had stood for an hour. It was somewhat less constant in the later stages of the disease. The question is raised whether this test may not be of value for early diagnosis.

5. Grafe, E. *Increase of Metabolism in Chronic Leukemia and Its Cause.*
6. Boehm, G. *Spastic Obstipation and Its Relation to Antiperistalsis.*

3. Schlayer in this study has taken up a series of cases which he designates as chronic vascular nephritis. His study seems to be a thorough one and is based on the study of the eliminative power of the kidney as shown by a study of water and salt excretion, and also sugar and potassium iodide excretion as representatives of foreign body substances. The weak point in the article seems to be the classification of the form of nephritis from a histopathologic point of view.

Of the chronic vascular nephritides two types exist: one accompanied with polyuria, the other with a diminished quantity of urine. The form with polyuria has a hypersensitive condition of the renal vessels and has low specific gravity irrespective of the intake of water. In this type the NaCl is excreted but always diluted. In the oliguric type the amount of fluid is diminished because of injury to the renal vessels and the NaCl cannot be excreted.

From a prognostic point of view this difference is important. In the one type the urine is highly concentrated; in the other not.

2. The potato has been advised in diabetes as the most easily assimulated of the carbohydrates. Some have advised that it be eaten in any quantity that may be desired. The authors show by experiment that such advise is unfounded, and, moreover, that potato in many instances produces a greater glycosuria than a similar amount of other of the purely carbohydrate foods. In conclusion they state most wisely that "Every diabetic has his personal coefficient for the utilization of carbohydrates, quantitatively as well as qualitatively. The physician cannot establish a proper treatment for his patient without determining first these two coefficients."

4. Santini concludes, from study of the literature and of a personal case, that in all forms of pyelitis, especially initial, therapeutic catheterism of the ureters and lavage of the pelvis should be tried before resorting to nephrotomy; that such maneuvre is free from danger, easy, and often sufficient alone to cure the patient, but that it should not be employed in neoplasm or tuberculosis of the pelvis. The most satisfactory substance for lavage is silver intrate in solutions of varying concentration. In forms where anäerobes are associated with colon bacillus, he proposes the use of hydrogen peroxide.

## Obituary.

### CARL BECK, M.D.

Dr. Carl Beck, a distinguished New York surgeon, died on June 8, at his country home at Pelham Heights, Westchester County. The immediate cause of death was pneumonia, although he had been suffering for some time from Bright's disease and diabetes. He was born at Neckargemuend, Germany, on April 4, 1856, and studied at the Universities of Heidelberg, Berlin and Jena, receiving his degree at Jena in 1879. He came to New York in 1882, and in a few years became widely known in the profession. In addition to his prominence as a surgeon, he was early recognized as an authority in x-ray work, which from the first he constantly employed in his public and private practice. He was professor of surgery and attending surgeon at the New York Post-Graduate Medical School and Hospital, attending surgeon and afterwards consulting surgeon to the German Poliklinik of New York, and attending surgeon to St. Mark's Hospital. Of the last-named institution he was president till January last, when he resigned on account of his failing health. He had great operative skill, and was the inventor of numerous useful surgical devices. He contributed many valuable papers to medical societies and journals, was the author of several excellent works in English and German, including "Roentgen Ray Diagnosis and Therapy," "Surgical Diseases of the Chest," and "Text Book on Fractures." Dr. Beck was a man of unusual culture, and his wide attainments, graceful presence, and suavity of manner made him universally popular. Among the positions of honor which he held were the presidency of the German Medical Society of New York, the American Therapeutic Society, and the Union of Old German Students of America. He is survived by a wife and three children, one of whom, Dr. Carl Eric Beck, is now attending surgeon to St. Mark's Hospital.

## Miscellany.

### A CIRCULAR CONCERNING ACUTE EPIDEMIC POLIOMYELITIS.

The following circular has been issued by the American Orthopedic Association and the American Pediatric Society in reference to acute epidemic poliomyelitis, and addressed to health authorities and boards of health

Anterior poliomyelitis is, so far as known, a communicable disease, being communicated from one patient to another and also by means of a third person. It occurs in epidemics and tends to spread along the lines of greatest travel. There is reason to believe that it is prevented from spreading by quarantine, and with the very great prevalence of the disease in the summer of 1910 it is the opinion of this committee that it is essential that it should be made a reportable disease in all states in order that its presence may be detected and its spread guarded against.

Of particular significance are the so-called aborative cases, where indefinite ailments occur in children in communities where frank paralysis also exists. These abortive cases of infantile paralysis are undoubtedly a source of infection, and their record and study is of much importance. In a community where cases of infantile paralysis occur cases of illness with sudden onset of fever and meningeal symptoms should be closely watched and regarded as possibly infectious. In such cases even recovery without paralysis does not establish the fact, that the case was not abortive infantile paralysis.

All cases of infantile paralysis should be strictly quarantined, sputum, urine and feces being disinfected, and the same rigid precautions being adopted as in scarlet fever. This quarantine should, in the opinion of the committee, last for four weeks in the absence of definite knowledge as to when the infection ends. Children from infected families should not be allowed to go to school until the quarantine is abandoned. The transportation or transfer of acute cases in public conveyances should be strictly forbidden. It would be very desirable to adopt provisional quarantine measures in suspicious cases in a community where an epidemic prevails. The report of all cases of infantile paralysis to the public health authorities should be enforced by the law, and all deaths from this cause should be properly described and registered. A careful study of epidemics by public health authorities is strongly advised.

(Signed)

Robert W. Lovett, M.D., *Chairman.*
Henry Koplik, M.D.,
H. Winnett Orr, M.D.,
Irving M. Snow, M.D., *Secretary.*

### INVESTIGATION OF ANTERIOR POLIOMYELITIS.

The Massachusetts State Board of Health has recently issued to physicians in this Commonwealth two circulars, one calling attention to the regulations of the board relative to the prophylaxis of ophthalmia neonatorum, the other outlining the plans of the board for continuing this summer its investigation of anterior poliomyelitis. The state legislature has approved an increased appropriation for this purpose, and the coöperation of all members of the profession is earnestly invited. Since Nov. 4, 1909, poliomyelitis hac been a notifiable disease, and during the epidemis

which may be expected this season the greatest promptness is urged in reporting suspected cases, and the greatest effort to secure permission for autopsy in those which prove fatal. For the guidance of physicians in treating the disease, the following points are particularly emphasized:

(1). The disease is infectious, though its etiologic agent is as yet unknown.

(2). The disease is contagious and patients should therefore be quarantined and their excreta disinfected.

(3). The disease is probably transmitted by third persons.

(4). Abortive or atypical cases are frequent.

(5). The use of hexamethylamine, is recommended in the treatment and prophylaxis of the disease.

## EXPERIMENTAL MEASLES IN THE MONKEY.

THE weekly report of the United States Public Health and Marine-Hospital Service for June 9, contains a preliminary communication from Dr. John F. Anderson, director of the hygienic laboratory at Washington, D. C., and Dr. Joseph Goldberger, on "Experimental Measles in the Monkey." An unsuccessful attempt to inoculate monkeys with measles was reported by Grünbaum in the issue of the *British Medical Journal* for April 9, 1904. The present authors report four series of similar experiments on rhesus monkeys, in which they produced moderate fibrile reaction, cough, and a sparse eruption. As a result they believe they "have demonstrated the susceptibility of the rhesus monkey to inoculation with the blood of human measles drawn from the general circulation early in the eruptive stage." This conclusion, if hereafter proved to be true, will be one more fact in the cumulating mass of evidence illustrating the close simian kinship of man.

## AIR SICKNESS IN AVIATION.

AN item in the Philadelphia *Public Legder* states that Dr. René Cruchet, of the University of Bordeaux, has recently presented before the French Academy of Sciences an explanation of certain accidents to aviators based on the supposition that they were overcome by "air sickness." This condition Dr. Cruchet described as analogous to mountain sickness and due to sudden changes in the atmospheric pressure. Aviators are said to be often affected, at altitudes over three thousand feet, with quickened respiration and heart-beat, headache, and nausea. In their descent, after partial temporary adaptation to a more rarefied atmosphere, the conditions are reversed, and the rapid increase of pressure leads to palpitation, suffocation, tinnitus, vertigo and somnolence. Dr. Cruchet believes that some of the fatal accidents have been due to the aviator's becoming momentarily unconscious from these physiologic phenomena and thereby losing control of his machine.

## RECORD OF MORTALITY

## SOCIETY NOTICE.

NATIONAL ASSOCIATION FOR THE STUDY OF EPILEPSY AND THE CARE AND TREATMENT OF EPILEPTICS. — The tenth annual meeting will be held in the rooms of the St. Louis Medical Society, St. Louis, Mo., June 16, 1911.

## RECENT DEATHS.

KELLEY, DANIEL JOSEPH, M.D., M.M.S.S., died in Worcester, June 10, 1911 aged fifty-two years.

DR. DANIEL M. DILL, of Newark, N. J., died on June 9, after a long illness. He was seventy years of age, and was graduated from the University of Michigan in 1867. For ten years he was superintendent of the Essex County Hospital for the Insane.

DR. EDWARD BURNETT VOORHEES, director of the New Jersey Agricultural Experiment Station at New Brunswick, and also professor of agriculture in Rutgers College, died from cerebral apoplexy on June 6. He was well known as an authority on milk supply and livestock, and was president of the Livestock Commission of New Jersey.

DR. JOSEPH PRICE, who died of appendicitis last week at Philadelphia, was born in Virginia in 1853. He had been prominent as a gynecologic surgeon and was one of the founders of the Gynecean Hospital in Philadelphia. He was a former president of the American Medical Association, of the American Association of Gynecologists, and of the American Society of Obstetricians, and contributed many articles to current medical publications.

DR. WILLIAM H. BERTRAM, who died last week of cerebral hemorrhage while visiting a patient in East Boston, was born in East Boston in 1849. He graduated from the College of Physicians and Surgeons, Boston, in 1891, and from the Tufts Medical School in 1895, since which time he has practiced his profession in East Boston. He was a member of the Eclectic Medical Society.

DR. FRANCIS M. CRAIGIN, who died of heart-disease last week at Norwood, Mass., was born in 1833. He received the degree of M.D. in 1860 from the Hahnemann Medical College, Philadelphia.

DR. JOHN LOUIS FORTIER, who died last week at Waterville, Me., was born at St. Sylvester, P. Q., Canada, on March 29, 1853. He moved to Waterville in 1880, and in 1883 received the degree of M.D. from the Humbolt Medical School at Brunswick, Me. Since this time he had practiced medicine in Waterville, where he was city physician for a number of years.

## Original Articles.

# THE RESULTS OF THE TREATMENT OF TWO THOUSAND CASES OF MISCARRIAGE AT THE BOSTON CITY HOSPITAL.

BY ERNEST BOYEN YOUNG, M.D.,

*Instructor in Gynecology, Harvard Medical School; First Assistant Visiting Surgeon for Diseases of Women, Boston City Hospital;*

AND

JOHN T. WILLIAMS, M.D., BOSTON.

As might be expected from the frequency of miscarriage, the literature upon the subject is voluminous, but consists largely of opinions expressed by various writers without giving statistics to support their views. The series of miscarriages upon which this article is based took place before the seventh month. The patients came from the same walk in life, and were not, for the most part, selected for hospital treatment because of complications, but most frequently because of unsuitable surroundings at home. Included with those in which miscarriage took place from natural causes are many in which pregnancy was interrupted by artificial means. Thus the tables represent a review of the incidence of miscarriage, its complications and the results of the treatment of these various classes of cases through a series of years.

In the early months, before the decidua reflexa has fused with the decidua vera, the fetus has been most frequently lost, the decidual lining of the uterus remaining to be cast off in small pieces, and but very rarely in our experience has the decidual lining of the uterus separated at the same time, or the ovum, shaggy with its chorionic villi, been expelled intact. Occasionally, at from two to three months an ovum has been expelled entire; but although by the processes of nature the fetus has, in most instances been cast off, we have found a tendency to retention of the secundines, which progressively decreases, however, with the duration of pregnancy.

It is the aim of the writers to publish the results in a large series of cases treated by fairly uniform methods, that the treatment employed and its results may be compared with those of others. According to the experience of the writers, no accident receives in the long run such poor attention either from patient or physician as miscarriage, and at the same time there are few common accidents which possess such possibilities as a cause of future invalidism.

The statistics show that very little advantage is attached to any particular method of emptying the uterus, but strict asepsis from the start and the avoidance of unnecessary traumatism must always play an important part in the end results. Too often the physician examines a patient without surgical cleanliness to learn whether a miscarriage is in progress, employing aseptic precautions only when it becomes necessary to empty the uterus. Thus the first examination may be the cause of sepsis in a miscarriage which would have otherwise proceeded to a normal convalescence.

Traumatism in emptying the uterus, especially in septic cases, is often insufficiently guarded against, as the extraction of even a small fetus through an imperfectly dilated os may cause tears almost as serious as at full term. It is the opinion of the writers that, even at the risk of some delay, a rigid contracted os is often better treated by a pack or bag rather than to risk the traumatism of the steel dilators. While the finger should always be used if possible, our results show that by a careful use of the dull curette in pulling out the retained placenta less harm is apt to come than from forcible dilatation to admit the finger.

One more point deserves especial mention — the avoidance of excessive loss of blood. Sepsis is more common after profuse hemorrhage, and in all women suffering severely from loss of blood it has been our practice to use the vaginal pack and defer operative procedure until the circulation has become readjusted. Among all the cases which have entered the hospital uninfected and reasonably early in the progress of the miscarriage, there has been but one death, the result of pulmonary embolism.

We shall not attempt a general review of the literature, which has already been made by Stowe,[1] but shall quote only from those papers which have contained statistics on the results of treatment, and not refer to those merely expressing opinions without giving evidence to support them.

Stowe [1] reviewed 750 cases from the Out-Door Department of the Chicago Lying-In Hospital. These were exclusive of profoundly septic patients, who were transferred to a general hospital. Of 411 cases, which could be included as inevitable or incomplete miscarriages according to our classification, 67 terminated spontaneously; 101 were cleaned out with the finger alone; 26 with finger and curette; 198 with curette alone, and 19 with placental forceps. In his entire series of 750 cases there were no deaths. Forty-two patients ran a temperature rising above 100.5 during the convalescence.

Magrier [2] reported 275 miscarriages, of which 176 terminated spontaneously and 99 by operation. One of the former was profoundly septic and died; the rest recovered. Of the latter, 55 were cleaned out with the finger and 44 with the curette. There were 6 deaths; 2 from perforation, 1 from salpingitis and 3 (all profoundly septic from the start) from general infection. He does not state whether the fatal cases were emptied with the finger or curette. Presumably those dying from perforation were curetted, and the 3 from general sepsis would have died under any method of treatment.

Fischer [3] reported 134 miscarriages, including 32 complete and 102 incomplete. Of the latter, 3 completed the miscarriage without interference, 69 were curetted and 30 cleaned out with the finger. All the cases made afebrile convalescences, although 13 had a temperature of 39.5° C. or over before delivery.

Lantos [4] reported 300 cases of miscarriage;

250 acute (all emptied by the finger except 4 with placental forceps) and 50 chronic cases (all curetted). Of the 246 acute cases cleaned out with the finger there were 211 clean cases with no deaths, but 2 instances of cellulitis. Of the 35 infected cases, there was one death from sepsis, and one case of pelvic peritonitis with recovery.

Hauff[5] in 275 miscarriages had 97 complete and 175 incomplete. Of the former, 2 developed parametritis, 1 pleurisy, and all recovered. The incomplete cases were all emptied with the finger except 13 (6 with finger and curette and 7 with placental forceps). There were 2 deaths from septicemia, and one patient developed parametritis but recovered.

Jacub[6] reported 53 miscarriages, in which 13 completed themselves spontaneously, and 40 were cleaned out with the finger. Of the latter, 4 cases were infected and 36 clean. One of each ran an elevated temperature during convalescence but recovered.

Franz[7] treated 709 out of 844 cases by curettage. He had one death from infection. Twenty-four cases had fever during the convalescence; one from advanced phthisis, one from parametritis, and the rest presumably from intra-uterine sepsis.

D'Erchia[8] reported 41 cases of incomplete miscarriage, all treated by curettage. There were no deaths and but 4 febrile convalescences; one due to lobar pneumonia, one to septic endometritis, and one to bilateral salpingitis.

Beuttner,[9] in 40 miscarriages, used the curette alone 27, the finger and curette eleven times, and the finger alone twice. Two of the first group which were infected on admission ran some elevation of temperature during convalescence. All of the 40 cases recovered.

The writers have analyzed the records of 2,000 consecutive patients admitted to the Gynecological Service of the Boston City Hospital for miscarriage or its complications. These extended over a period of thirteen years from 1896 to 1910. We have not included threatened miscarriages which quieted down under treatment. We have classified the various cases under six headings: Complete, incomplete, infected beginning and inevitable miscarriages, and infections following and subinvolution after miscarriage.

Under complete miscarriages are classed those in which the uterus had emptied itself spontaneously of its entire contents before the patient entered the hospitals; under incomplete, those in which the fetus had been expelled but all or part of the placenta and membranes still remained in utero; under infected beginning miscarriages, those in which nothing had yet been thrown off by the uterus but the presence of infection made it dangerous to attempt to save the pregnancy; and under inevitable, those in which the entire ovum still remained in utero, but in which the extent of dilatation or the amount of hemorrhage made it impossible to prevent miscarriage. Under infections following miscarriage are included those cases admitted with well-marked septic conditions already present which were the immediate reason for entering the hospital. Under subinvolution are included all cases where flowing had continued for one month or longer, but in which the uterus, although enlarged, was found empty when curetted.

The result of this classification in the 2,000 cases was as follows:

| | |
|---|---|
| Complete miscarriages, | 199 |
| Incomplete miscarriages, | 1,333 |
| Infected beginning miscarriages, | 111 |
| Inevitable miscarriages, | 151 |
| Infections following miscarriages, | 135 |
| Subinvolution following miscarriage, | 71 |

The first thing to be considered in the treatment of miscarriage is the ability of the uterus to empty itself spontaneously. Excluding the cases in which infection determined the necessity for interference there are 1,683 in which to study this point. These cases were interfered with only when nature failed to empty the uterus or the loss of blood became so great as to endanger the patient's life.

| Period of pregnancy. | Total number. | Completed spontaneously. Number. | Per cent. |
|---|---|---|---|
| One month to eight weeks, | 233 | 35 | 10.1 |
| Two months, | 565 | 63 | 11.1 |
| Three months, | 536 | 70 | 13.0 |
| Four months, | 214 | 28 | 13.0 |
| Five months, | 85 | 14 | 16.4 |
| Six months, | 50 | 13 | 26.0 |
| Total, | 1,683 | 223 | Average, 13.2% |

From the foregoing table it will be seen, first, that about 13.2% of all miscarriages may be expected to complete themselves spontaneously; and, second, that the likelihood of a miscarriage to be completed without interference increases in direct proportion to the duration of pregnancy. This is somewhat contrary to the common statement that before the placenta is developed the ovum is likely to be thrown off intact. It is undoubtedly true that such an occurrence takes place in a large number of cases which never seek surgical treatment, but it is nevertheless true that it has been distinctly rare in our experience at the hospital to find an intact ovum expelled.

With few exceptions the cases were all treated according to the following methods. Miscarriages which had completed themselves spontaneously before admission were treated expectantly, the uterus being entered only if signs of infection appeared. In incomplete miscarriages during the fifth to eighth weeks of pregnancy the uterus was cleaned out with a large dull curette, dilating the cervix if necessary with branched dilators sufficiently to admit the passage of the curette. The placental tissue was "raked" out carefully until the uterus seemed to be empty and then the walls lightly gone over with a sharp curette. Later in pregnancy the cervix was dilated with the steel dilators if necessary and the finger introduced. The uterine contents were removed as far as possible with the finger, and the process then completed with the dull curette.

Inevitable and septic beginning miscarriages

were allowed to complete themselves spontaneously when possible. When interference became necessary, the same rules were followed as in incomplete except that in these cases dilatation of the cervix often presented much difficulty. When the cervix was extremely rigid a tight vaginal pack was introduced and left for twenty-four hours before attempting to empty the uterus. In many cases even as late as the third and fourth months dilation of the cervix to a size sufficient to admit the finger was so difficult and dangerous that the attempt was given up and the fetus and placenta both removed piecemeal with the clamp and curette as a much safer procedure.

Packing the cervix and vagina to promote expulsion of the uterine contents was tried only thirty-four times. It was successful without other treatment eight times in 26 inevitable miscarriages, but was used eight times without success in incomplete miscarriages. While it is thus seen that packing is an often unsuccessful method of emptying the uterus, it has two very distinct and valuable uses. The first of these is to soften a rigid cervix as a preliminary to dilatation and curettage. The other is in patients exsanguinated from hemorrhage; to control the bleeding and allow them to rally from the initial loss of blood before emptying the uterus. Five women who were practically pulseless on admission were treated in this way and recovered.

The cases admitted for infections following miscarriage were treated by measures appropriate to the conditions present. Those of subinvolution were, with few exceptions, curetted.

All cases having a temperature of 100.5° F. or over on admission are considered to be infected; and the same temperature, persisting for twenty-four hours or longer taken as a standard of morbidity in the convalescences. The total results of treatment are as follows: The cases without elevation of temperature at entrance numbered 1,331. Excluding two patients moribund on admission from hemorrhage and dying within one hour, and one death from alcoholism to which the miscarriage had no contributing influence, there was only one death, from pulmonary embolism on the second day. The mortality of clean cases was, therefore, 7-100 of 1%, the mortality from sepsis being 0.

Excluding the cases admitted primarily for infections following miscarriage, there were 523 infected cases. Among these there were 6 deaths; 3 developing diffuse peritonitis, one pyemia, one septicemia, and one dying from pulmonary embolism. The mortality of infected cases subjected to treatment fairly early was, therefore, only 1 6-100%. The cases admitted for infections following miscarriage will be taken up later.

The following figures show the liability of miscarriages at the various months to become infected, and the influence of the duration of pregnancy and size of the uterus upon the mortality. The first table shows the number of cases without temperature and with temperature entering the hospital; and the number of each having septic convalescences.

| Period of pregnancy. | Total number. | Cases without temperature on admission. | | Cases with temperature of 100.5 or over on admission. | |
|---|---|---|---|---|---|
| | | Number cases. | No. septic convalescences. | Number cases. | No. septic convalescences. |
| One month to eight weeks, | 279 | 177 | 1 | 102 | 31 |
| Two months, | 651 | 435 | 11 | 216 | 52 |
| Three months, | 635 | 431 | 26 | 204 | 70 |
| Four months, | 256 | 183 | 22 | 73 | 25 |
| Five months, | 110 | 65 | 4 | 45 | 16 |
| Six months, | 69 | 51 | 4 | 18 | 12 |
| Total, | 2,000 | 1,342 | 68 | 658 | 206 |

The second table shows the percentages of the total number of miscarriages, by months, which became infected, which made septic convalescences, and in which death from sepsis occurred.

| Period of pregnancy. | Percentage with temperature 100.5 or over at entrance. | Percentage septic convalescence. | Percentage mortality. |
|---|---|---|---|
| One month to eight weeks, | 36.5 | 11.4 | 3.5 |
| Two months, | 33.1 | 9.6 | 3.5 |
| Three months, | 32.1 | 15.1 | 3.4 |
| Four months, | 28.5 | 18.0 | 3.1 |
| Five months, | 40.9 | 18.1 | 3.6 |
| Six months, | 26.0 | 23.1 | 7.1 |

From the foregoing tables it is seen that there is:

(1) decreasing percentage of infected cases in miscarriages at successive months.

(2) An increasing percentage of sepsis in the convalescence.

(3) A fairly constant mortality. The high mortality of the six months miscarriages was obtained in such a small number of cases that unless it can be verified at some future time in a larger series it must be disregarded as probably an accidental variation.

In the following tables the writers set forth the results of treatment in miscarriages entering the hospital at different stages.

| | | |
|---|---|---|
| Complete miscarriages, | | 199 |
| Cases without elevation of temperature on admission, | | 159 |
| With afebrile convalescence, | 156 | |
| With transient rise of temperature, not over twenty-four hours' duration, | 1 | |
| With septic convalescence, | 2 | |
| Case with temperature of 100.5 or over on admission, | | 40 |

| | | |
|---|---|---|
| With temperature normal within forty-eight hours, | 27 | |
| Temperature normal in forty-eight hours to one week, | 6 | |
| Septic convalescence, | 6 | |
| Temperature due to outside causes: | | |
| Pulmonary tuberculosis, | 1 | |
| Incomplete miscarriages, | | 1,333 |
| Cases without elevation of temperature on admission, | | 952 |
| Afebrile convalescence | 866 | |
| Transient rise of temperature, not over twenty-four hours' duration, | 35 | |
| Septic convalescence, | 51 | |
| Cases with temperature of 100.5 or over on admission, | | 381 |
| Temperature normal within forty-eight hours, | 289 | |
| Temperature normal within forty-eight hours to one week, | 37 | |
| Septic convalescence, | 47 | |
| Temperature due to outside causes: | | |
| Lobar pneumonia, | 3 | |
| Pulmonary tuberculosis, | 2 | |
| Typhoid, | 1 | |
| Septic arm, | 2 | |
| Infected beginning miscarriages, | | 111 |
| Cases delivering themselves spontaneously, | | 19 |
| Temperature normal within forty-eight hours, | 17 | |
| Septic convalescence, | 2 | |
| Cases expelling fetus spontaneously, secundines, removed, | | 23 |
| Temperature normal within forty-eight hours, | 20 | |
| Septic convalescence, | 3 | |
| Cases in which the entire ovum was removed artificially, | | 69 |
| Temperature normal within forty-eight hours, | 46 | |
| Temperature normal in forty-eight hours to one week, | 10 | |
| Septic convalescence, | 13 | |
| Inevitable miscarriages, | | 151 |
| Cases delivering selves spontaneously after packing, | | 7 |
| Afebrile convalescence, | 5 | |
| Septic convalescence, | 2 | |
| Cases delivering selves spontaneously without interference, | | 40 |
| Afebrile convalescence, | 39 | |
| Septic convalescence, | 1 | |
| Fetus expelled spontaneously, placenta removed, | | 24 |
| Afebrile convalescence, | 21 | |
| Transient rise of temperature, not over twenty-four hours' duration, | 2 | |
| Septic convalescence, | 1 | |
| Both fetus and secundines removed artificially, | | 73 |
| Afebrile convalescence, | 63 | |
| Transient rise of temperature, not over twenty-four hours' duration, | 5 | |
| Septic convalescence, | 5 | |
| Complicated by other conditions, | | 4 |
| Typhoid, | 2 | |
| Tuberculosis, | 1 | |
| Alcoholism, | 1 | |

The table at the bottom of this page shows the incidence of the various septic conditions in the four classes of cases just tabulated.

The mortality in these cases was as follows:

| | | |
|---|---|---|
| Complete miscarriages, | | 0 |
| Incomplete miscarriages, | | 8 |
| Cases without temperature: | | |
| Hemorrhage (moribund on entrance), | 2 | |
| Pulmonary embolism, | 1 | |
| Cases with temperature over 100.5 on entrance: | | |
| Septic endometritis, acute dilatation heart, | 1 | |
| Septic endometritis, pulmonary embolism, | 1 | |
| Diffuse, peritonitis, | 3 | |
| Infected beginning miscarriages, | | 2 |
| Delivered of fetus and placenta artificially: | | |
| Septicemia, | 1 | |
| Pyemia, | 1 | |
| Inevitable miscarriages, | | 0 |

These figures speak for themselves. The greatest morbidity and mortality was found in the incomplete and infected beginning miscarriages as would be expected, since they were the most difficult cases; but even on these when the patients arrived at the hospital early, the results were extremely good. As our cases were practically all cleaned out by the same method, we cannot in this series draw any comparison between the different methods of artificially emptying the uterus. We shall have, however, the opportunity to compare the results of interference with those of spontaneous emptying of the uterus in the table on the following page. These figures and percentages include only the cases with a temperature of 100.5 or over on entrance.

From the above it would appear that the important thing in an infected case is to empty the uterus. The method makes no difference. That the results of interference are no better than of spontaneous completion of the miscarriage does not appear to be a reproach to our methods, for we interfere only when nature fails. On the contrary, it is gratifying that the artificial

| | Septic endometritis. | Pelvic cellulitis. | Pelvic abscess. | Salpingitis. | Diffuse peritonitis. | Multiple arthritis. | Phlebitis. | Cellulitis and phlebitis. | Septic endometritis, pulmonary embolism. | Gonorrhea. | Sloughing fibroid. | Septicemia. | Pyemia. |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| Complete: | | | | | | | | | | | | | |
| Without temperature, | 2 | | | | | | | | | | | | |
| With temperature 100.5 or over, | 3 | 2 | | 1 | | | | | | | | | |
| Incomplete: | | | | | | | | | | | | | |
| Without temperature, | 38 | 5 | | 5 | | | | | | 2 | 1 | | |
| With temperature 100.5 or over, | 9 | 15 | 1 | 12 | 4 | 3 | 1 | 1 | 1 | | | | |
| Infected beginning, | 13 | 1 | | 1 | | | 1 | | | | | 1 | 1 |
| Inevitable, | 5 | | | 2 | | | 1 | | | | 1 | | |
| | 70 | 23 | 1 | 21 | 4 | 3 | 3 | 1 | 1 | 2 | 2 | 1 | 1 |

| | Total number. | Temperature normal within forty-eight hours. | Temperature normal in two days to one week. | Septic convalescence. |
|---|---|---|---|---|
| In numbers: | | | | |
| Uterus emptied spontaneously, | 58 | 44 | 6 | 8 |
| Uterus emptied artificially, | 465 | 355 | 47 | 63 |
| In percentages: | | | | |
| Uterus emptied spontaneously, | – | 75.8 | 10.3 | 13.8 |
| Uterus emptied artificially, | – | 76.3 | 10.1 | 13.5 |

results have been as good as where the entire process has been completed naturally.

Seventy-one patients were treated for subinvolution following a miscarriage. Of 16 cases at one month to eight weeks; 26 at two months; 19 at three months; 6 at four months and 2 each at five and six months. Practically all were curetted with relief.

Space will not permit a detailed discussion of the treatment of infections following miscarriage. At entrance, all cases without evidences of inflammatory process in the Fallopian tubes or broad ligaments were given an intra-uterine douche. Fresh air, forced feeding and stimulation formed an important part of the routine treatment. Vaccines and antistreptococcic serum were also tried out. When pus was present in the broad ligament or peritoneal cavity it was evacuated by the nearest route. In a later paper the writers hope to consider the treatment of septic cases in greater detail.

The pathological lesions present in these cases and their mortality is shown in the following table.

| Condition present. | Number Cases. | Number deaths. |
|---|---|---|
| General septicemia without local suppuration, | 46 | 46 |
| General septicemia with septic pneumonia, | 4 | 2 |
| General septicemia with phlebitis, | 1 | 1 |
| General septicemia with phlebitis, cellulitis, arthritis, | 2 | 0 |
| General septicemia with cellulitis and arthritis, | 1 | 1 |
| General septicemia with subcutaneous abscess, | 3 | 2 |
| General septicemia with secondary hemorrhage, from sloughing endometrium, | 1 | 1 |
| Diffuse peritonitis, | 12 | 11 |
| Salpingitis, | 12 | 0 |
| Septic endometritis, | 26 | 1 |
| Pelvic cellulitis, | 16 | 0 |
| Pelvic cellulitis, and phlebitis, | 1 | 0 |
| Pelvic abscess, | 9 | 3 |
| Phlebitis, | 1 | 0 |
| Total, | 135 | 68 |

Finally, a word as to the self-induced and criminal abortions. Whatever one's moral attitude toward these procedures, their danger is evident. Out of 2,000 cases, 55 admitted the use of drugs, 262 self-induction by instrumentation, and 147 criminal abortion. Of the self-induced, 56.4%, and of the criminal, 50%, were infected. Of the former, 14.9%, and of the latter, 25.8%, made septic convalescences. The mortality of the self-induced cases was 5.7%, and of the criminal abortion 10.2%.

A wide variety of implements were used, the most common being the soft rubber catheter. The most deadly was the douche nozzle, which, probably infected by previous use in an unclean vagina, was employed thirty-three times with 15% mortality. Other implements which served to produce abortion were the uterine sound and curette, knitting needle, penholder, lead pencil, bougie, umbrella point, slippery-elm stick, wire, hatpin, tree twig and the finger.

Space has necessitated presenting these statistics very briefly, but it is our belief that the inferences drawn from them are correct. While there are undoubtedly many cases of miscarriage which do perfectly well without surgical treatment, the writers believe that the cases included in this series were representative ones. The almost uniformly satisfactory results obtained in the cases received early and the number of previously untreated, or poorly treated, cases which arrived at the hospital late in the miscarriage and hopelessly septic, lead us to recommend the application of the surgical principles of rest and asepsis to every case and interference when it becomes indicated. The writers believe that the following conclusions are justified.

## CONCLUSIONS.

1. Spontaneous emptying of the uterus takes place in but about 13.2% of all miscarr ages.

2. The likelihood of a miscarriage to complete itself increases with the duration of pregnancy.

3. When it becomes necessary to use artificial means to complete the miscarriage, the finger followed by the curette in later miscarriages, and of the curette alone in the earlier months of pregnancy has given uniformly satisfactory results at the Boston City Hospital.

4 Experience has shown that where the cervix is extremely rigid it is better to introduce the curette and break up the fetus and placenta and remove them piecemeal than to attempt to dilate the cervix sufficiently to introduce the finger.

5. Packing the vagina and lower segment of the uterus is an unsatisfactory and often unsuccessful method of emptying the uterus. No success whatever was obtained in treating incomplete miscarriages in this way.

6. Packing is, however, of great value in two classes of cases.

First, in exsanguinated patients, to stop the hemorrhage and give the woman a chance to recover somewhat from the loss of blood before emptying the uterus.

Second, when the cervix is very rigid, a tight cervical pack for twenty-four hours will soften it so that dilatation may be attempted with safety.

7. The results of artificial methods are as good, but not better than where nature has succeeded in emptying the uterus.

8. Artificial methods are necessary in a majority of cases, however, simply because nature has failed.

9. In infected cases the essential thing is to get rid of the infectious material by emptying the uterus; the particular method employed making little difference.

10. The later in pregnancy miscarriage occurs the smaller the liability to become infected, but the greater the likelihood of developing grave septic complications if infection does take place.

11. The mortality is practically the same at all periods of pregnancy.

12. Induced abortions have a greater mortality than accidental. The mortality of patients admitted to the hospital after criminal abortions was 10%.

## FURTHER EXPERIENCE WITH THE BENZIDIN TEST FOR OCCULT BLOOD IN DISEASES OF THE DIGESTIVE ORGANS.*

BY FRANKLIN W. WHITE, M.D.,

*Instructor in Clinical Medicine, Harvard University; Second Assistant Visiting Physician, Boston City Hospital.*

THE subject of tests for blood in gastric contents and feces needs no introduction. We have all used them and know their value. The only question is which test to use and how to interpret results.

I reported my early experience with the benzidin test over a year ago.[1] I felt then that it had some advantages over the guaiac test. The technic was simpler, the results clearer and the somewhat greater delicacy was an advantage in detecting traces of blood in different types of ulceration.

The benzidin test has been used widely since then and additional favorable reports have appeared by Schumm, Citron, Clark, Walter, Merkel, McWeeny and others.

*Delicacy.* — Like all recent tests for blood, the delicacy varies greatly according to the technic used, and the literature of the subject is confusing because these tests are now being used for medico-legal as well as clinical work. In medico-legal work the greatest possible delicacy is desired; in clinical work this is not the case.

The original benzidin test is far too delicate for clinical work. Schumm's modification of the guaiac test is not only too elaborate, but also too delicate. These tests give positive results in feces for three or four or more days after eating a single piece of meat. They are confusing. We must choose a less delicate technic.

*We must not go too far in the other direction.* The Weber guaiac test commonly used is a rather rough test and often does not detect blood when it is present.

If the stools of a healthy person eating meat once or twice a day are examined by the ordinary Weber guaiac test, we get a negative result two thirds of the time. It is easy to understand why a test which frequently gives negative results when ¼ to ½ lb. of meat is eaten, will frequently leave us in the lurch in peptic ulcer and cancer.

The largest series of tests of stomach contents I have seen reported where the guaiac test was used were by Graham and Guthrie, of the Mayo's clinic. These cases were all serious chronic ulcerative ones which came to operation.

Statistics are given in 150 cases of cancer of the stomach. This group was not composed of early cases. The symptoms had lasted over a year, more than one half the cases had palpable tumor and nearly one half had marked pyloric obstruction.

Figures are given in 250 cases of chronic peptic ulcer. (Probably more than one half of these were *duodenal* ulcer which helps explain the low per cent. of cases with blood in the stomach contents.)

In 150 cases of cancer of the stomach, blood was present in 80 cases, or 53%.

In 250 cases of chronic peptic ulcer, blood was present in 49 cases, or 20%.

Their experience seems to justify their conclusion that "three fourths of all ulcers must be diagnosticated without blood findings," (with the guaiac test).

I think such results with meat diet and with chronic ulceration show that the guaiac test is not delicate enough for our work. Some one may object that the guaiac test might be delicate because it shows 1 part of blood in 8,000 of water, but we must remember that the delicacy of the guaiac test and of all the recent blood tests is greatly reduced by the presence of organic material such as occur in stomach contents and feces. The guaiac test, for example, will only show 1 part of blood in 200 to 500 in feces.

We want a happy medium between the rather rough guaiac test and the over-sensitive original benzidin test, and I believe this is found in Schlesinger and Holtz modification of the benzidin test.

In my first year's work with the benzidin test I used the guaiac test constantly to control results. In the last year I have used the benzidin test alone for all routine work.

*Technic.* — The Schlesinger and Holtz method reduces the delicacy of the original Adler benzidin test by using a small amount (2 to 3 drops) of the material for examination, and excludes oxidizing ferments as a source of error by boiling. The technic is as follows:

The material for examination consists of simple gastric contents; or of a pea-sized piece of feces thoroughly stirred in a test tube into about 4 ccm. of water. This is brought to a boil to destroy oxidizing ferments. Ten drops of a fresh solution of benzidin (prepared by shaking a knife-tip of benzidin in about 2 ccm. of glacial

* Read at the fourteenth annual meeting of the American Gastro-Enterological Association, Philadelphia, April 19, 1911.

[1] A Comparison of the Guaiac and Benzidin Tests for Invisible Hemorrhage in Diseases of the Digestive Organs. BOSTON MED. AND SURG. JOUR., 1909, clx, pp. 733-743.

acetic acid) is added to 3 ccm. of a 3% (ordinary commercial solution) of hydrogen peroxide in a test tube. This mixture serves as a control of the cleanliness of reagents and glassware.

To make the test, add 2 or 3 drops of the boiled gastric contents or of the feces mixture to the peroxide benzidin mixture. A clear green or blue color appears within a minute or two when blood is present. I have added the drops of material to be examined without shaking the mixture, in which case a deep ring of color develops only at the top. This gives a sharper result when little blood is present.

The method is simple and rapid and easily learned. It can be performed within five minutes. With pure reagents the results are uniform and reliable. The color changes are clear and sharp even in feces, because very little fecal pigment is present to interfere. The ether extraction of the guaiac test is replaced by the simple quick method of boiling.

It is best to use only pure reagents of best quality and to avoid peroxide solutions containing acetanelid as a preservative. I use dioxygen. The glassware must be scrupulously clean. It is unnecessary to neutralize the reaction of gastric contents or feces.

It is very rare to find feces which give a positive reaction (due to oxidizing ferments or drugs) in the absence of blood, and it saves time to examine feces as a routine without boiling and only boil if the unboiled specimen is positive.

*Precautions.* — The usual precautions about food were taken. Foods containing hemoglobin (meat, fish and their juices) were excluded from the diet for two days where the feces were tested. Where the stomach contents were examined after a test breakfast, no previous exclusion of meat, etc., was needed except in cases of marked pyloric stenosis.

With reference to drugs, hemoglobin preparations, iodides and salts of iron were omitted during the tests.

*Clinical Results.* — The cases quoted are almost all private cases, and the examinations were all made either by the author or under his immediate supervision. Only those cases are included in which the diagnosis was practically certain from long clinical observation, or as the result of operation or autopsy.

Two hospital cases in which tests were made by the author were excluded because of a reasonable doubt about the use of a meat and fish-free diet. They were unintelligent Italian laborers.

In the previous series 334 examinations were made in 126 cases. To this we now add 608 examinations in 164 cases, making a total of 942 examinations in 290 cases. We shall present all the cases in one group since the technic of the test and the precautions observed were identical in both series.

I have tabulated the results as simply as possible, dividing the cases into ulcerative and non-ulcerative. For convenience, healthy persons on a meat diet, and hepatic cirrhosis are put with the ulcerative cases, and healthy persons on a blood-free diet, with non-ulcerative cases. I will not discuss the results in detail in different diseases, but simply emphasize a few important points.

The uniform negative results in the 273 examinations of feces in the 217 non-ulcerative cases show that this modification of the benzidin test cannot be charged with being too delicate for clinical work. Misleading positive results are absent. In about one fifth of the stomach contents in these cases a minute trace of blood results from the use of the tube. This is about equally true with the guaiac test and seems unavoidable.

Blood was found in *every examination* of the feces of healthy persons on a meat diet.

Blood was found in *all but two* cases of chronic peptic ulcer.

Blood was found in *every examination in every case of cancer* of the stomach or bowel examined. These are clearer, more uniform results than I have seen reported with the guaiac test, or that I have been able to get with it myself. The contrast between ulcerative and non-ulcerative cases is sharper. *In my opinion they show that the benzidin test has more value than any other blood test in detecting chronic ulceration in the digestive tract.*

We know that the benzidin test is far more reliable in detecting traces of blood from the food in the feces of healthy persons, and it is natural to find it is also more reliable in detecting traces of blood from an ulcerated surface.

Chronic peptic ulcers are characterized by intermittent bleeding, and we see from the table that about one half of the specimens of feces and gastric contents examined in these cases were negative, but it is not surprising that some positive results were obtained in almost every case when we consider that the patients were almost without exception referred to me at a time when they were at their worst, when the ulcers were most irritated or inflamed and most likely to bleed.

The only case classed as chronic gastric ulcer which gave only negative blood tests was a patient who was examined at a time of pain and distress of one week's duration a year after a gastro-enterostomy had been performed. The patient was entirely well for months before and after this brief attack, and it is more than doubtful whether an open ulcer was present at the time of examination.

The only duodenal ulcer which gave only negative blood tests was a patient who gave a long history of acute attacks with complete intermissions of several months between. He was not seen in the active stage, but at a time when there had been no symptoms for a month, and unfortunately only one examination of feces could be made. An operation three months later showed a chronic ulcer.

In these cases of chronic peptic ulcer the delicacy of the benzidin test was very useful in diagnosis. I have seen a few indurated ulcers which gave only negative results with the guaiac test,

but I believe this much less likely to happen with the benzidin test. Thus far I have not seen a single case where uniformly negative tests with benzidin were followed immediately by the disclosure of an open chronic ulcer at operation. (We must never be content with a single examination of feces or gastric contents in chronic peptic ulcer.)

I realize that my statistics on the benzidin test for blood in chronic peptic ulcer will be more valuable when the series is larger. I should like to see the benzidin test given a thorough trial in some of the surgical clinics where large numbers of these cases are annually operated upon.

In cases of acute ulcer the feces were usually examined till three consecutive negative results were obtained. The feces usually became negative for blood in acute cases with hematemesis in about ten days after hospital treatment was begun.

In one case of benign stenosis of the pylorus, the three positive results in the gastric contents were due to the meat remaining from previous meals. In the other the two positive results probably came from erosions caused by the irritation of the stagnating food.

The cancers of the bowel were distributed as follows: one of the jejunum, one of hepatic flexure, one of the splenic flexure, and one of the sigmoid. General experience has shown that with the guaiac test, positive results have been less constant and frequent in cancer of the bowel than in cancer of the stomach. Our experience with the benzidin test in these few cases of cancer of the bowel has given equally constant positive results.

The invariable positive results in cancer need a word of explanation. They are probably due to the fact that all these cases were seen in consultation and unfortunately were well developed when I first examined them. In 9 of these cases the diagnosis was obvious from the history, tumor, pyloric obstruction and loss of weight. It is grossly unfair to the test, however, to say that it only appears when other signs are unmistakable. Positive results probably are obtained as soon as ulceration begins, which is usually early in gastro-intestinal cancer. Fully one half of these cases were doubtful latent ones without either tumor, obstruction or marked loss of weight, and the constant presence of occult blood was very valuable in diagnosis.

On the other hand, we may fairly conclude from these results that if a patient suspected of cancer has had time to develop an ulcerated lesion, and repeated examination with the benzidin test gives only negative results, this is strong (but not absolute) evidence against the presence of cancer. I have seen many such cases in the past few years.

The positive results in cirrhosis have little or no diagnostic value and may be misleading.

*The Phenolphtalein Test.* — I should like to say a few words about the phenolphtalein test for blood, though I have used it only a short time.

I was kept from trying it by early reports of French authors who found it extremely delicate, much more than the original benzidin test, giving a positive reaction with one part of blood in one or two millions in watery solutions, and said to show the presence of even *congestion* of the mucous membranes.

Since Boas' paper was published in January, 1911, recommending the test and placing it midway between the guaiac and benzidin tests in delicacy, I have given it a trial.

The reagent is simply made by dissolving 1 or 2 gm. of phenolphtalein and 25 gm. of potassium hydroxide in 100 ccm. of water and heating gently till decolorized in the presence of 10 gm. of powdered zinc. The solution is permanent.

The test is made by adding 2 ccm. of gastric contents or feces and water, previously boiled and *cooled*, to 1 ccm. of the reagent and a few drops of hydrogen peroxide. A prompt red or pink color is positive.

The sources of error in general are the same as for the benzidin test and similarly excluded by diet and boiling. ***Heat alone will give a positive test and must be avoided.***

My short experience has shown that the test is *less* delicate than the benzidin test, and *more* delicate than the guaiac test, if approximately the same technic is used for all, — but a comparison of the usual phenolphtalein test (using 2 ccm. of material to be examined and 1 ccm. of reagent) with the Schlesinger and Holtz modification of the benzidin test shows that they are much alike in delicacy. The phenolphtalein test is a little more delicate for blood in watery solutions and in gastric contents, and almost exactly the same for blood in feces. As in the benzidin test, the presence of organic material (feces, gastric contents) greatly reduces its delicacy.

It seems to be a good test, simple and clear, but I can see no advantage over the benzidin test; the slight advantage of having a permanent solution of the phenolphtalein reagent is counterbalanced by other slight disadvantages, such as the necessity for cooling the material for examination after heating, etc. I must use the test more before giving a final opinion.

Boas advises making an ether extract of the material to be examined instead of boiling it, to exclude sources of error such as oxidizing ferments. This is a step backward; boiling answers the purpose, is simpler and shorter and is to be preferred.

In conclusion, I do not wish to exaggerate the importance of blood examinations. Nothing could be worse than to jump at conclusions in a case from a few blood tests. I always look with the greatest care for all other signs and symptoms of ulceration.

We all realize the difficulties of interpretation of results. We know that benign cases with blood in the stomach are not always ulcer, and that negative results do not always exclude chronic ulcer. We realize that there is an early stage in every cancer that is non-ulcerative, and that scirrhous cancer may ulcerate late.

Piles and other rectal diseases are a great nuisance, at times preventing the use of blood tests

in the feces, but in spite of all I find that blood tests are a very great help in clinical diagnosis, and I believe that the Schlesinger and Holtz benzidin test is the best one to use, on account of its simplicity, clearness and degree of delicacy.

## ON THE RELATION BETWEEN LABORATORY WORK AND CLINICAL WORK.*

BY RICHARD C. CABOT, M.D., BOSTON.

I SHALL try first to distinguish the real differences from the fancied differences between these two classes of work; next I shall endeavor to point out what seem to me to be the proper relations between the two branches.

### I. SUPPOSED DIFFERENCES.

In almost any group of physicians who discuss the subjects that grow out of hospital work and medical teaching one hears a distinction made between the so-called laboratory branches of work and the laboratory men on the one hand, and the clinical branches and clinical men on the other. In the Harvard faculty, for instance, one constantly hears such a distinction emphasized, and there come near to being two parties within the faculty divided on these lines and voting quite consistently as groups.

1. The prevailing idea, I think, among men who use these terms is that laboratory work is *exact science*, while clinical work is rough and *inexact science;* that laboratory work is done with instruments of precision, while clinical work is done with our eyes, our fingers, our ears and other still more inaccurate instruments. Doubtless this distinction holds true in many laboratories and in much clinical work, but there is no essential reason why it should be so, and in many hospitals it is not so. For example, the measurements of weight, temperature, blood pressure, may be as exact in the wards as anywhere else. They are all clinical procedures, yet all carried out with instruments of precision. It is true further that many of the procedures ordinarily carried out in the wards could be carried out in the laboratory, and vice versa. At the Massachusetts General Hospital we have small ward laboratories in which a good deal of the work on the blood is done close at the bedside. I have seen similar work in Johns Hopkins Hospital.

A considerable amount of laboratory work concerns itself with animal experimentation, and this, I suppose, will never be carried on in the wards or be called clinical; but I do not suppose that any one wishes to limit the term "laboratory work" to animal experimentation. On the other hand, the attitude of mind and the processes of thought used in animal experimentation are frequently applied at the bedside.

2. This brings me to a second distinction sometimes present in the minds of those who divide themselves into a laboratory group and a clinical group in a college faculty or any other body which is likely to discuss these questions. I refer to the distinction between (*a*) relatively *passive observation* such as one may use as he watches the course of a fever, and (*b*) the relatively active *construction and verification of hypotheses* which (in the great majority of problems studied in the laboratory) are concerned with animal experimentation. This last type of thought and work is sometimes said to be especially characteristic of the laboratory, while the relatively passive type is identified with clinical work.

This distinction, however, like that previously referred to, seems to me fallacious. One can and constantly does make experiments on patients; in fact, every item of therapeutics is in a very real sense an experiment, and if the mind of the clinician is active he is constantly forming and testing hypotheses in this as in other parts of his work. It is true that as a group clinicians are more apt to be men of the passively observing type than are the best type of laboratory workers, but this is a distinction which has no good ground for existing and which it ought to be the endeavor of all of us who care for either branch of work to wipe out.

In the laboratory one has no work unless he sets himself some problem, thinks out some hypothesis which he wishes to verify. On the other hand, in the wards one can and many do keep busy without forming or testing out any hypotheses worthy of the name. That is only to say that for some people it is easier to go to sleep about one's work in the wards than it is in the laboratory. On the other hand, it is clear to all of us who know much of laboratories that there are considerable areas of laboratory work in which the exercise of actual intelligence approaches the zero point. I refer, of course, to the mere purely technical repetition of processes previously

* Read before the Quis Medical Society of New York, Feb. 11, 1911.

worked out by others and the verification by a long series of similar experiments of hypotheses thought out by some one else, and often of doubtful value. *The high grade type of work* in the laboratory *is the construction of fruitful hypotheses;* their verification may involve further exercise of first-class brain power in the elaboration of methods, but in practice it often does not.

Summing, up, then, the supposed but, I think, unreal differences between laboratory work and clinical work I should say that if we are talking of *good* work in both fields, we cannot differentiate them by criteria or accuracy nor by the type of mental process employed in the two fields of work. In the laboratory and at the bedside there are relatively accurate measurements carried on with instruments of precision and relatively inaccurate judgments made without instruments; in both fields we must employ the mental processes of relatively passive observation and the processes of constructing and verifying hypotheses, if we are to do good work.

## II.

Turning now to the real differences which, so far as I can see, will always exist, and ought to exist between laboratory work and clinical work, we may say that they consist essentially in this: *in the wards, as in practice of medicine outside a hospital, psychical elements are everywhere present, and are often paramount, while in the laboratory they are reduced to the minimum.* Deeply embedded in every item of the evidence which we secure when we take a patient's history in the wards, are psychical factors, psychical data, psychical judgments, psychical pressure exerted on both sides of the relation. The nature of the questions asked and their effect upon the patient's mind, the skill with which we interpret his answers, paying due regard to racial elements, to local habits of speech, to differences in age and sex, and to the patient's various prejudices, preconceptions and fears, — all these elements are essentially psychical and incapable, so far as one can see at present, of being automatically registered or exactly measured. The personality of the patient and of the physician is a factor and a variable factor in every observation and in every record.

Still more obviously is this true when one turns to the treatment of disease. Whereas in the laboratory one's constant effort is to reduce the personal factor, the personal equation, to a minimum, to remove from the field of vision all elements due to one's own personality, and to make oneself so far as possible passive before the phenomena which we are trying to record, the opposite is true of every successful clinician. He can never take the passive attitude if he is to do the best for his patient. He must always be trying to push the facts in some special direction, to interfere with the course of nature, and to make himself count. In my own work I have often felt a sort of wrench as in dealing with patients I have turned from the activities of physical diagnosis with their strenuous efforts at impartiality and passivity, to the field of active therapeutics in which one succeeds only by being partial, not impartial, by taking chances and by the presence of a contagious hopefulness.

It seems to me most important that we should recognize this as the essential difference between laboratory work and clinical work. We shall understand, then, why it is that the first-class laboratory worker or the man who in the earlier stages of his medical course shows up brilliantly in anatomy, physiology and physiological chemistry is yet often a total failure when it comes to clinical work. One may be a paragon of excellence in those fields of medicine where skill in the give and take between personalities counts for little that is, in the laboratory, and yet be unfitted for clinical work.

In clinical work a different sort of training is necessary if we are to go beyond instinct and the light of nature in the processes of human intercourse on which a considerable portion of the successful diagnosis and treatment of disease depends. Most skilful clinicians are quite unaware of the complexity and difficulty of the psychical art which they constantly practice. In the investigation of the patient's past history and present complaints it has been often pointed out that the skill required is properly to be compared to that of a cross-examining lawyer, but I think it has many other phases equally difficult and equally important. I see no good reason why training might not be provided in this branch of the art of medicine, why skilled clinicians should not become conscious and communicative with the methods and devices which they have been using all their lives for the attainment of truth and the avoidance of gross error in questioning patients.

Of course we are all familiar with the type of man who says, "After all, the history is not of much value; we never can depend upon what the patient says; we must rest our whole case upon the results of physical examination." Such a man may be sincere, but he certainly does not know what he is talking about. All the best diagnosticians that I know are agreed that in certain diseases, for example, in gallstone disease, and in most diseases of the stomach, the history is of far more value than the physical examination. This state of things is, of course, more obvious but not more real when we come to deal with diseases of the nervous system, especially with those ordinarily called functional, and with all that fall within the realm of the alienist; but I think there is hardly an important group of diseases in the whole list in which the diagnosis may not be seriously affected by the manner in which the history is obtained. Indeed, I think clinicians are agreed that there is fully as much skill demanded and used in history taking as in physical examination.

It is not quite true to state as some do that in the wards we are dealing with life and in the laboratory with dead things; of course much that we deal with in the laboratory is alive. But I think it would be true to say that the essential

difference between laboratory work and clinical work consists in this; that in the wards psychical elements are mixed up with all of the data both of observation and of treatment, while in the laboratory psychical data are reduced to the minimum and may be often measured in the form of some type of personal equation which can then be allowed for in our conclusions. Personally, I believe that this difficulty should be recognized in our medical curricula and that more training should be given in the psychical dexterity to extract a good history and to give effective treatment.

### III. WHAT SHOULD BE THE PROPER RELATION BETWEEN CLINICAL WORK AND LABORATORY WORK WITHIN A HOSPITAL?

It is obvious at the outset that we are here dealing with a problem of medical specialization. All the functions now separately performed by two sets of men, one in the laboratory and the other in the wards, were originally part of the work of a single group of men, and in some cases this is still true. Some of the English clinicians, for example, make their own autopsies and follow the tissues through. Yet I suppose we must recognize that this form of specialism has come to stay and, on the whole, if properly safeguarded, it makes for good work. What I wish now especially to insist upon is that this form of specialism, like all forms of specialism, brings with it particular evils as well as particular benefits, and that if we are to enjoy these benefits and avoid those evils, we must elaborate special methods, special apparatus *for neutralizing the evils*. If I may borrow a phrase from Sherrington whose remarkable work on the integrating function of the nervous system is doubtless familiar to you all, I should say that medical specialism within the hospital calls for special *integrating factors* if we are to get the good of it and not to run foul of obvious disasters. Some of the evils at which I have hinted are doubtless familiar to all of us. Not to dwell on the more obvious and avoidable types of evil, such as the mixing up of specimens in a laboratory, I will mention three points. First: many clinicians are incapable of utilizing the data given them by the laboratory expert. Secondly, many laboratory experts confess in moments of frankness that without some knowledge of the clinical aspects of the case they cannot make the decision which is asked of them as a result of their study of tissues.

Thirdly, many of us have been troubled by a lack of correlation between the ante-mortem and post-mortem facts. The man who does the autopsy often lacks interest in the special questions which have concerned the clinician during the patient's lifetime, and is reprehensibly indifferent regarding causes of death. On the other hand, we all of us can recall clinicians who calmly allow diagnoses to stand upon the clinical record after they have been flatly contradicted by the autopsy findings.

I will now take up these points somewhat more in detail.

(*a*) I am often astounded at the innocent confidence which is exhibited by clinicians when dealing with laboratory data concerning the examination of the blood, stomach contents, urine and feces. I see towering structures of therapeutic effort based upon laboratory findings which will not bear the strain. The interpretation of a hemoglobin measurement, of a Wassermann reaction, of a guaiac test, by clinicians is quite different in case that clinician chances himself to have done some of the work necessary to perform these tests. Unless one knows by actual experience the sources of error, the degree of accuracy, the kind of significance which any such test involves, he is quite incapable of using it at the bedside as an aid to his clinical work.

I do not mean to suggest that the clinician should do all these tests himself in each of the cases which he undertakes to attend and to treat, but I do most emphatically assert that no clinician can use effectively as a part of his clinical judgments, any physical, chemical or microscopic test which he has not himself performed often enough to know it intimately. In no other way can he understand where he can bear his whole weight and where he must step cautiously.

Occasionally men go to the other extreme. I have known a surgeon cut down upon an enlarged liver, despite the fact that he had seen in his clinical record of that patient a typical report of leukemic blood. This wholly unnecessary operation was performed because the surgeon was skeptical — in this case over-skeptical — of the value of laboratory tests. He might have known that a leukemic blood constitution is as certain as any fact in science; as certain, that is, in the conclusions which should be drawn from it regarding prognosis and treatment. On the other hand, I have seen a clinician base both diagnosis and treatment upon a single guaiac test in the feces, made without any knowledge of the patient's diet or the condition of his rectum. I have seen a negative Wassermann reaction taken as proper ground for abandoning anti-specific treatment.

But the laboratory worker also needs clinical data. Fragments of tissue from the prostate, from the uterus or from an enlarged gland will be more satisfactorily studied by a pathologist who has won in the wards an interest and comprehension of the patient whence the tissues come.

Further, the clinician and the man who does the autopsy need to get together more, both before and after the patient's death. In many autopsies the pathological items from different parts of the body and different systems of organs are written down in the summary of the autopsy findings, quite without any suggestion of which is the most important. One may study such protocols without getting any idea as to the causes of death and the sequence of events. This sort of impartiality seems to me quite unjustifiable. It would not occur, I think, if the pathologist had seen the patient often enough during life to acquire a genuine interest in the diagnostic problem involved. How did the disease start? What is to

be regarded as "complication" and what as the "original source" of the trouble? What is the cause of certain symptoms, of mysterious pains here and there, of sudden dyspnea, of unexplained cyanosis? What was the immediate cause of death? No physician has a right to neglect these questions merely because he calls himself a pathologist. The writing down of isolated items of pathologic anatomy in a summary of an autopsy protocol is a caricature of science, not the genuine article.

On the other hand, I have known physicians whose interest in the patient's disease ceased wih the patient's death. Wholly erroneous diagnoses thus remain upon the record book, uncorrected by the results of the post-mortem examination. As an extreme case, I remember a diagnosis of neurasthenia written upon a hospital record and remaining there until this day, although the autopsy showed that all the symptoms attributed to neurasthenia were, in fact, due to a cancer of the pleura of which the patient died.

## IV.

I think I have said enough to recall to our minds the evils which are familiar to us all, the evils of unguarded specialism in the field of hospital work. I turn now to consider what can be done to prevent these evils.

I have said above that in a hospital, as in the human body, effectiveness depends upon the presence of some integrating factor whch will prevent specialism from running wild and will remind the different parts of the system that they must be members of one body if they are to be of any use. At the Johns Hopkins Hospital we may recongize that for many years the integrating factors were the personalities of Dr. Osler and Dr. Welch. These wonderful men held together the whole system, prevented the laboratory specialist from being a mere laboratory man, and kept the clinician properly ashamed of his ignorance. I do not suppose such institutions as Dr. Osler and Dr. Welch can be made permanent in every hospital. They represent special providences, special mercies upon the part of nature which are not likely to be often repeated. Is it possible that the hospital superintendent might furnish such a factor of integration? Certainly not, so long as the present conception of his duties holds good. College presidents sometimes act as integrating factors, controlling the unrestrained specialism of the different departments, and it is perfectly conceivable that by a total change in our conception of the functions of the hospital superintendent he might come in this way to be a most essential factor in the success of the hospital's medical work. I do not say that this ought to be done; I merely say that it might be done, and if it is not done we must do something else and not drop the problem because it cannot be solved in this way.

I recently had occasion to observe how among the disintegrated units of an out-patient department, an integrating influence was introduced by the presence of a layman, a social worker, who happened to observe that patients treated for some weeks in the nerve room as cases of nervous prostration, turned up later in the department for tuberculosis because they were so obviously tuberculous that even the nerve specialists could not longer overlook the fact. This occurrence would have been wholly unknown to both departments and would have passed unnoticed but for the integrating presence of the social worker who passed unscathed through all departments and noted what she saw.

But if we cannot depend upon any such genius as Dr. Welch, nor upon a reformed hospital superintendent, nor upon a social worker, as an integrating factor in our hospital system, something may be done by the method used in the West Medical Service at the Massachusetts General Hospital during the past year, namely, by combined ward visits of a clinician, pathologist and others, by whose views our ward problems may be elucidated. Dr. J. H. Wright, director of our pathological laboratory, has made regular weekly visits in the wards with the visiting physician and his assistants, has read the histories of puzzling cases, sometimes making an examination himself or directing the point and method for the excision of some bit of tissue which needs examination. His point of view has been of constant value to the clinician, and I have no doubt has added to his own interest in the autopsy findings. We have also obtained much of value from the visits of Dr. Boos, the pathological chemist of the hospital, whose suggestions along pharmacological and therapeutic lines have been especialy valuable.

We need, however, to extend this system much further. We should have regular weekly or bi-weekly visits of a neurologist, a physiologist and a surgeon, not separately but always in conjunction with the clinician; and, of course, I am equally convinced that the physician should make rounds with the surgeon in the latter's wards, and should be a frequent visitor in the pathological laboratory, not only to learn the results of post-mortem examinations, but to familiarize himself with the technic of the physical, chemical and biological tests, the results of which he is required to interpret at the bedside.

Out of such combined ward visits is sure to come freer and more fruitful discussion of cases, better service to patients, a livelier scientific and practical interest all along the line.

### SUMMARY AND CONCLUSIONS.

(1) The essential difference between clinical work and laboratory work is not in the technical methods employed, nor in the degree of their accuracy, nor in the methods of reasoning used. The essential difference consists in the predominance of psychical elements among the data used in the wards, and their elimination in the laboratory.

(2) The clinician cannot safely utilize at the bedside, the results of laboratory tests which he knows only by reading. He should familiarize himself with these tests in the laboratory, in

order to understand the sources of error and the limits of reliability.

(3) No laboratory worker should remain out of touch with the clinical aspects of the cases which furnish him his material.

(4) In the absence of any single dominating personality as an integrating factor in the hospital system, the best available substitute seems to be *combined ward visits* in which the pathologist, surgeon, physician, chemist and physiologist work together for the increase of their practical and scientific fruitfulness. The evils of specialism may be thus in a measure neutralized and its benefits enjoyed.

## SHORT RÉSUMÉ OF THE HISTORY OF CÆSAREAN SECTION.*

BY ELIZABETH T. GRAY, M.D.,
*Visiting Surgeon to New England Hospital.*

CÆSAREAN Section is an operation for the delivery of the child at term by means of an incision through the abdominal and uterine walls. This is supposed to be an operation of great antiquity. It is commonly assumed that it takes its name from Cæsar who is said to have come into the world in this way. Pliny mentions several other celebrities, Scipio Africanus and Manlius, who were born in this same manner. These early histories, however, are possibly mythical. But undoubtedly the practice of Cæsarean section dates back to prehistoric times.

A Roman law, ascribed to Numa Pompilius, made it obligatory upon physicians to remove the child by abdominal section in case the mother died during pregnancy.

During the Middle Ages, the Roman Church adopted this law, for by means of it they sought to rescue the child, that the rite of baptism might be bestowed upon it.

To-day it is forbidden in Austria to bury a woman, dying in the second half of pregnancy, without first performing Cæsarean section with all the care and technical skill used in operating during life, in hopes of either saving the child or at least of baptizing it.

Cæsarean section performed *just before* life was extinct has been reported as successful in saving the child, by Runge, in maternal brain tumor, by Frank in maternal general burns, by Sommerbrodt in maternal fibrosarcoma cerebri, by Hay in cerebral apoplexy, and E. P. Davis, of Philadelphia, has reported the delivery of a living child five minutes after the mother had died of eclampsia.

It having been shown that many children were saved in this way after the death of the mother, the question arose whether it would not often be right in cases of protracted labor, and where the life of the child, although not that of the mother, was threatened. This proposal met with bitter opposition and it was urged that to open the abdomen of the mother, even if her condition was hopeless, in order to save the life of the child, was a criminal procedure, and Virchow cites an instance in which a physician was prosecuted for performing Cæsarean section on a dying woman with hope of saving the child.

The first *recorded* Cæsarean section on a living woman was performed in the year 1500 by one Jacob Nufer, a butcher, who is said to have saved the life of his wife in this way. It is further stated that he operated many times later on other women.

In 1581 François Roussett published histories of fourteen successful Cæsarean sections, six of which were said to have been performed on the same woman. The authenticity of this report is doubtful.

About this time history shows that the operation was several times successfully performed, and many operators hastened to perform it without the proper indications. We are told that for a short time in Italy it became almost as common as blood-letting. Under these conditions a reaction soon set in and the operation fell into disrepute.

Later fresh proof was brought forward to show that it might be safe if performed by skillful hands. Undoubtedly this work of the seventeenth century in Cæsarean section has been greatly exaggerated by historians.

Women have performed Cæsarean section upon themselves. Harris reports that in one hundred and nineteen years six women have successfully performed this operation upon themselves.

The operation has been accidentally performed upon women, far advanced in pregnancy, by rips from horns of cattle. Harris also reports eleven cases of women ripped open by horned animals, eight of whom escaped death. The inhabitants of some of the uncivilized countries, notably in Central Africa, are known to have performed this operation, the result being favorable to both mother and child. Palm wine was the fluid used to wash the abdomen of the patient and the hands of the operator. The abdominal wound was closed by long pins, just as it was closed by the older operator among civilized nations, and sutures were placed over the pins in the figure-of-eight fashion.

The earliest well-authenticated case of Cæsarean section comes from Germany in 1610, by Trautman. The patient lived about three weeks after operation. No doubt was entertained with regard to her recovery. However, contrary to expectation, on the twenty-fifth day after the operation she suddenly became faint and died within half an hour.

Until very recently Cæsarean section was justly regarded as one of the most hazardous operations in surgery. Up to 1873 only from 37% to 40% of the operations resulted in recovery. Spaeth, writing about this time (1873), said: "There has not been a single case in the lying-in hospitals of Vienna in this century which has terminated favorably for the mother." Godson states, in this same year, that for over one hundred years there was not a single successful case in

* Read before the New England Hospital Medical Society, Boston, Nov. 17, 1910.

Vienna, and he, with other authorities, make the same claim for Paris. During about this same period Chiaria, of Milan, is credited with sixty-two operations, three of which were successful. The responsibility for these results was due, first, to septic infection, the evils of which were especially felt in hospital practice, and second to the postponement of the operation until the patient was almost moribund. Another great factor in preventing success was the persistent idea that the alternate contraction and relaxation of the uterus forbade the use of the uterine suture; consequently the wound in the uterus was left to gape open, and closure in the few favorable cases was brought about by an inflammatory process which bound the uterus to the abdominal walls.

So strong was this idea that only a comparatively short time ago Porro proposed to avoid the risks of the gaping of the uterine incision by the removal of the uterus at the time of the section, after the delivery of the child.

The operation to-day takes its place among the most successful of surgical procedures, and American surgeons have done much to put it in this position. The success of the present-day Cæsarean section is due largely to the following factors:

First, strict aseptic precautions.

Second, early resort to operation before the patient's strength has been exhausted by lengthy efforts to extract the child by the natural passages.

Third, to the careful and complete closure of the uterine incision.

Fourth, to a *perfected technic.*

In contrast to the reports of the results of the operation, previous to 1873, Edward Reynolds reports as known to him personally thirty operations with thirty recoveries. To obtain such results it is of vital importance that the operation should be undertaken early, that the operator should be familiar with every detail, that it must not be undertaken as a last resort. It must be a conservative procedure, undertaken to save the lives of both mother and child.

Carefully examined statistics show that if undertaken as above the mortality to the mother is no higher than from uncomplicated oöphorectomy and to the child *nil.*

A résumé of the statistics of Leopold, Olshausen and Zweifel show a mortality of 5.8% for the conservative operation, and 3.7% for the Porro.

We find, in difficult forcep deliveries, from 1 to 3% mortality to mother and 25 to 30% to child, and it is a well-known fact that many of the infants who survive this forcep extraction are seriously injured for life.

There are two men who are so closely connected with the history of the modern Cæsarean section that we speak of the operation as the *Porro-Cæsarean* or the *Sanger-Cæsarean.* About 1876, when the maternal mortality was so great that the operation was practically condemmed, Porro, of Milan, introduced his method, in which the operation of Cæsarean section was accompanied by the amputation of the uterus. It is claimed that before Porro operated upon women in this way, he and Spaeth, of Vienna, experimented successfully upon dogs and rabbits. Statistics now showed that this was a very successful procedure and at this time gave a far better showing than the operation in which the uterus was left behind.

Sanger, of Leipzig, now insisted that the suturing of the uterine wall was essential, and after careful suturing was carried out the results were as favorable as in the Porro, without the mutilation of the latter operation.

Undoubtedly in those years when *all* abdominal surgery was dangerous and infection carried off a large percentage of the cases the Porro was a safer operation than the conservative Sanger. Surgical practice has now changed so largely that these two operations have become complemental to each other and are no longer rivals in the same field.

The Porro should be performed when some morbid element makes it dangerous to keep the uterus in the body. Present-day statistics are teaching us that the mortality is lower in those cases where the operation is performed a second or third time upon the same patient than with the first operation, probably because these last operations are operations of election, and so a more favorable time and better preparation is obtainable than in the first operation.

A few cases have been reported where each patient was operated upon successfully four times.

The results of a successful Cæsarean section are so brilliant that there is danger that the pendulum may swing too far on the side of this operation and we must be careful to remember that the section should only be resorted to when the indications are clearly defined, and only after the most thorough preparations have been instituted for its performance and the proper assistance obtained.

## INDICATIONS FOR CÆSAREAN SECTION.

BY MARY FORRESTER HOBART, M.D.,

*Attending Physician to the New England Hospital for Women and Children.*

It may truly be said that the practice of medicine is now dominated by the surgeon. In early times, the surgeon was pre-eminently the "bone doctor." To set fractures, to reduce dislocations and to amputate was his special province. Beyond these functions he was seldom in demand. Now, it is quite a different matter. His co-operation is not only a necessity, but without it we dare not proceed too far.

If we have a doubtful brain lesion, he trephines; if we are treating rhinitis, he removes the turbinates; our pale, delicate children grow rosy after an operation for adenoids and tonsils; our patients with persistent pain between the shoulders have their scapulæ trmmed off, and when we are struggling with the digestive and genito-urinary tract, nothing escapes his zeal. Cases of apparently simple indigestion are found to depend on appendicitis, acute or chronic, or on duodenal ulcer, or gallstones. These recover more quickly

under the surgeon's knife than by ringing the changes on taka-diastase or the Bulgarian bacillus. Those patients who waited in the physician's office year in and year out for pelvic treatment now seek relief by oöphorectomy and ventral suspension. Cystoscopy brings the surgeon face to face with the urinary tract and calculi and neoplasms of kidneys and bladder.

Even from obstetrics the surgeon is no longer excluded, but is frequently summoned to aid the accoucheur.

The indications for Cæsarean section have been classified by various writers as absolute and relative.

The absolute remains, and ever will remain, unaltered, viz., maternal or fetal dystocia, rendering the removal of the fetus, unless by embryotomy, impossible.

Formerly Cæsarean section was performed only after the death of the mother, and instances are recorded of the delivery of a living child as late as twenty-three minutes after maternal death. This is still occasionally done, but must, of course, follow immediately the mother's death.

Under absolute indications would also be classed extremely narrow or deformed pelvis, the presence of tumors blocking the genital tract, such as uterine fibromata, ovarian cysts, or pelvic exostoses, and pathological conditions of the cervix causing rigidity of the os.

During labor the absolute necessity may arise, especially in an emergency case, where no antipartem examination has been made, — an abnormally large child, or a child disproportioned to the size of the pelvis, — or the maternal forces may fail making some interference necessary. Here we have a choice between Cæsarean section and embryotomy Twenty years ago, the former would have been only rarely considered, but we feel that with the aseptic technic that so generally prevails to-day, we not only save the child, but give the mother a better chance, than by dragging a mutilated baby through a contracted pelvis.

Cæsarean section after death of the child has been considered bad practice, but now it often seems wiser, because quicker and more aseptic for the mother.

A pelvis with true conjugate of 6.3 cm. is a positive indication for Cæsarean, even with a small child; while with a fully or over-developed child, 7 cm. would just as surely demand Cæsarean.

The day is over when only a conjugate of 7.5 cm. warrants the capital operation. We have many borderland cases.

It is with the relative indications that the obstetrician most frequently deals, and antepartem conditions must be carefully considered for both mother and child. A diminished conjugate, between 8 and 9 cm. with a child developing normally in size, indicates induction of labor at thirty-four to thirty-six weeks, or Cæsarean section at term.

Induced labor with it necessary manipulation, — possibly instrumental delivery and a premature baby, — seem to present greater risk for both mother and child than an aseptic and rapid Cæsarean section.

In older primiparæ we often find the desire for childbearing intense and the death of the baby would be a great misfortune. In such cases, we often have more or less rigidity of the soft tissues of the pelvis, associated with diminished measurements. Hence we advise Cæsarean as giving the full-term baby the best chance for life.

Cæsarean section in eclampsia is now coming to the front for consideration.

Recently, at the Maternity of the New England Hospital, we have had two such cases, — both primagravidæ, — both were transferred from the medical ward after convulsions had set in; each patient had a rigid, uneffaced cervix. In the first case, we spent several hours in ineffectual attempts to dilate the os uteri; manual and instrumental dilation were both tried, but it was absolutely impossible to dilate the os sufficiently for version or forceps Cæsarean section was performed — the premature baby lived one or two days; the mother, a few days longer.

The second case was transferred at once to the surgical ward with excellent results for both mother and child.

In case of eclampia in a multigravida or in a primagravida with elastic, dilatable cervix, the radical operation would hardly be considered.

For placenta previa, Cæsarean section at this present time seems more serious than prudent. Although advocated by some writers, it is regarded as a doubtful proceeding by conservative obstetricians. In the future, should our technic be still further improved, it may be more favorably considered.

## TECHNIC OF THE OPERATION.*

BY MARY A. SMITH, M.D.,

*Visiting Surgeon to New England Hospital.*

THE term "Cæsarean section" is applied to several operations, with varying technic. An intelligent selection from these demands also consideration of the alternative operations, viz., laparo-eletrotomy, symphyseotomy, hebosteotomy and craniotomy.

The degree of pelvic contraction, the stage of labor and the condition of the patient are vital factors in the decision. Thomas' laparo-eletrotomy — a suprapubic delivery of the cervix into the abdominal wound — avoids incision into the uterus, but is too complicated for general adoption. Symphyseotomy and hebosteotomy, while applicable in cases of moderate pelvic contraction (not below 7 cm.), demand the use of special instruments and trained assistants. They involve danger of injury to the bladder and blood vessels, frequently causing severe hemorrhage at the time, and thrombus or hematoma later, or, through non-union, permanent or serious disablement. Hammerschlag estimates that 10% of these cases are followed by thrombus and 19.5% by hematoma, while the maternal mor-

* Read before the New England Hospital Medical Society, Nov 17, 1910.

tality is 10% and the child's 9%. Hebosteotomy has the advantage that a patient may be allowed to enter upon labor and given a chance of natural delivery, with the certainty of being able to terminate the same should the pains prove ineffectual, or the patient show signs of exhaustion. On the other hand, it requires full dilatation of cervix, and usually the necessity of version or forceps for delivery of child.

It has been estimated that 20% of epileptics and children in hospitals for the feeble-minded were delivered by high forceps, and bone fractures and other injuries to the child are not uncommon.

Craniotomy has fallen into great disrepute except in case of a dead child. Vaginal Cæsarean was brought out by Dühessen in 1896. The special indications for it are in maternal cardiac disease, stenosis of cancer of cervix and especially in eclampsia with rigid cervix. It requires trained assistants as the technic is rather complicated, a roomy pelvis, and requires more time than an abdominal section. It remains to be proven whether the scars in the cervix and lower uterine segment will interfere with subsequent pregnancies more or less than those in the fundus of the uterus. It is very much favored by German and French surgeons. Williams reported nine cases in 1909, and favors it.

To avoid hemorrhage, the incisions should be made in the exact median line, and long enough for the easy extraction of the child, as a tear at the upper end extending obliquely might give rise to excessive hemorrhage. After delivery of child and placenta, reintroduce speculum and draw down on the traction sutures till the whole wound is brought well into view. Begin sewing at the top of the incisions, taking the posterior one first, and pack the uterine cavity with gauze to insure good contraction of the uterus before sewing up the anterior incision. Afterwards sew up the rents in the vagina.

Latzto makes an incision in the lower part of abdomen, pushes aside the bladder and peritoneum, divides the left vesical ligament and makes an extraperitoneal Cæsarean operation, especially good in late cases, and if they have become infected, he drains first and sews up the incisions later. Porro was the first to deliberately plan and carry out the removal of the pregnant uterus, 1879. It has the disadvantage of sterilizing, the woman when more children are desired, but is the operation of choice in infected cases, or where tumors are present which make a future pregnancy undesirable.

The technic is the same as for the Sänger operation up to the removal of the child, and after that the same as in any suprapubic hysterectomy. The mortality of this operation was at first about 50%, but is now very much less. Since the details of the so-called conservative Sänger-Cæsarean have been perfected (1882), this has become the operation of choice with the large majority of surgeons. By it the maternal mortality has been reduced to 2 or 3% and practically all healthy children delivered at term should survive. Moreover, it may be repeated many times in the same patient without serious damage to the uterus provided it has been well sewed up and no infection taken place.

BEST TIME FOR PERFORMING CÆSAREAN SECTION.

It was formerly thought necessary to wait till labor had begun and the cervix well dilated in order to assure proper uterine contraction and avoid hemorrhage. But it was later found that the vitality of the uterine fibers becomes exhausted by prolonged contractions of same, and is not conducive to good healing. Moreover, it has been found to be unnecessary, so while in the interest of the child it is well to delay till the end of pregnancy in uncomplicated cases, the operator may then set the time for his convenience. Preparations for Cæsarean section are about the same as for other abdominal operations. Asepsis is, of course, of prime importance. Very few instruments are required. Scalpel, scissors, hemostatic forceps with needles and suture materials are amply sufficient.

The abdominal incision most frequently employed is in the median line and to the left of the umbilicus, from one half to one third being above same, and from one half to two thirds below it. It is hardly worth while to waste time in applying hemostats, as simple pressure with the gauze sponges is sufficient. The sponges also protect the abdominal cavity from being soiled with either blood or aminotic fluid. In uninfected cases it is unnecessary to remove the uterus from the abdomen. Fritsch and some others prefer to incise the uterus transversely in the fundus from one tube to the other, and a few make an incision in the posterior uterine wall in order to avoid adhesions to the abdominal wall, but most surgeons make a clean cut in the fundus and prolong the incision in the anterior wall just far enough to permit the extraction of the child. If possible, avoid the placental site, which in one half the cases is in front, but if not, do not cut through it, but loosen up quickly on one side, rupture the aminotic membrane if fluid is not already gone, seize child, preferably by the feet, and extract same. The cord is then doubly clamped and cut between, and the child is taken away to be resuscitated by an assistant, if necessary, but often it cries out before leaving the table. If head should become wedged in cervix and does not readily yield to traction from above, an assistant must push it up from the vagina.

It is unnecessary to pass a rubber ligature around the cervix, but an assistant may grasp a broad ligament in either hand and by pressing firmly down against the cervix compress the vessels to avoid hemorrhage. Meantime the operator removes the placenta and wipes out the uterine cavity, another assistant grasps the fundus with both hands and holds it firmly while the wound is being sewed. A hypodermic of ergotale is now in order. Up to this time not more than from one to two minutes has been consumed, and while no undue haste should be used, still there should be no delays between the consecutive steps in the

operation. The sutures may be of linen, silk or tendon but never of catgut, as such knots are apt to loosen as the muscle fibers shrink, or are too rapidly absorbed before healing is complete. The first row of sutures should enter a little back of the edge of the wound under the peritoneal covering, and pass through the whole thickness of the uterine muscle to but not through the mucosa, reversing the process on the opposite side, and be immediately tied. They should be about 1 cm. apart. The second row of sutures should also be interrupted and sufficient in number to accurately bring the peritoneal edges together over the deeper layer, which are thus lost to sight.

In clean cases one may draw the omentum down over the uterus to prevent adhesions to the abdominal wall, or in septic cases better to put it behind to protect the intestines, as sepsis is most likely to show itself by breaking through the line of incision.

The abdominal wound should be closed with layer sutures, and dressed like any other abdominal wound. Firm support to the wound and much comfort to the patient may be given by applying a broad strip of adhesive plaster on either side. These are laced together by means of shoe hooks fastened into the edge of same and can be unlaced to remove the sutures or adjust the dressings. The patient wears this until she is ready to be discharged, when she is fitted with some form of abdominal support.

The after care is the same as for any puerperal case.

## THE IMMEDIATE RESULTS OF CÆSAREAN SECTION.*

BY JOHN T. WILLIAMS, M.D., BOSTON.

FOR permission to use the statistics from the Boston Lying-In Hospital I am indebted to Dr. Charles M. Green, visiting physician, and I furthermore wish to acknowledge my obligation to Drs. Newell, Swain, Friedman, Torbert, Mason and De Normandie, of the hospital staff, for the use of their cases.

Although Cæsarean section has been performed sporadically for three centuries, it is only within the last fifteen to twenty years that the results have been such as to justify its use in any except the most extreme cases of pelvic contraction.

Budin [1] is authority for the statement that every Cæsarean section performed in Paris between the years 1787 and 1876 resulted fatally. Contrasted with this is Reynold's [2] series of thirty personal cases without a single death, reported in 1907. The reasons for this improvement in results are:

1. The introduction of asepsis.
2. The introduction of uterine suture.
3. The proper selection of cases.

The importance of the first two of these factors is obvious and needs no further mention. It is chiefly with the consideration of the third that I shall deal in this paper.

* Read by invitation before the New England Hospital Medical Society, Nov. 17, 1910.

Three years ago Reynolds [2] collected all the reported cases of Cæsarean section performed during the preceding ten years by obstetricians who had done at least five operations. He classified them all under three headings: Primary, secondary and late sections. He called those operations performed before the onset of labor, primary; those done early in the first stage, secondary; and those done after six hours of strong pains, twenty-four hours of trifling pains, or in which the os was dilated more than the size of a half dollar, late Cæsarean sections. I have taken the cases collected by Reynolds, and added to them all which I could find similarly reported since, and including 100 published [3] and 44 hitherto unpublished operations at the Boston Lying-In Hospital. The results with regard to maternal mortality appear in the following table:

| | Primary. | | Secondary. | | Late | |
|---|---|---|---|---|---|---|
| Author. | Cases. | Deaths. | Cases. | Deaths. | Cases. | Deaths. |
| Reynolds,[2] | 82 | 1 | 158 | 6 | 49 | 6 |
| B. L. H., | 75 | 3 | 37 | 3 | 32 | 6 |
| McPherson,[4] | 2 | 0 | 40 | 5 | 107 | 17 |
| Polak,[5] | 4 | 0 | 4 | 1 | 6 | 0 |
| Spalding,[6] | 2 | 0 | 2 | 0 | 3 | 0 |
| Frederick,[7] | 2 | 0 | 1 | 0 | 1 | 0 |
| Kynoch,[8] | 5 | 1 | 0 | 0 | 0 | 0 |
| Reddy,[9] | 0 | 0 | 2 | 0 | 3 | 0 |
| Canton,[10] | 0 | 0 | 2 | 0 | 6 | 0 |
| Wallace,[11] | 9 | 0 | 4 | 0 | 3 | 1 |
| Reid,[12] | 1 | 0 | 2 | 0 | 1 | 0 |
| Mouchotte,[13] | 0 | 0 | 8 | 0 | 6 | 0 |
| Boyd,[14] | 3 | 0 | 1 | 0 | 2 | 0 |
| | 185 | 5 | 261 | 15 | 219 | 30 |

These figures show definitely that the mortality of Cæsarean section increases in direct proportion to the length of time in labor, being 2.7% in the primary, 5.7% in the secondary and 13.7 % in the late operation. The causes of death were as follows:

| | Primary. | Secondary. | Late. | Total. |
|---|---|---|---|---|
| General peritonitis, | 3 | 6 | 16 | 25 |
| Uterine sepsis, | 0 | 0 | 4 | 4 |
| Septicemia and pyemia | 0 | 3 | 0 | 3 |
| Thrombosis and embolism, | 0 | 1 | 1 | 2 |
| Pneumonia, | 1 | 2 | 4 | 7 |
| Hemorrhage, | 1 | 0 | 0 | 1 |
| Shock, | 0 | 0 | 2 | 2 |
| Rupture of uterus, | 0 | 0 | 1 | 1 |
| Intestinal obstruction, | 0 | 0 | 1 | 1 |
| Acute dilation of stomach, | 0 | 1 | 0 | 1 |
| Chronic nephritis, | 0 | 1 | 1 | 2 |
| Paraplegia from Pott's disease, | 0 | 1 | 0 | 1 |
| | 5 | 15 | 30 | 50 |

In those patients who recovered, the morbidity of the convalescence also increased in proportion to the duration of labor, being 5% in the primary, 6.5 % in the secondary and 10.5 % in the late sections, as shown in the following table.

| | Primary. | Secondary. | Late. |
|---|---|---|---|
| Wound sepsis, | 4 | 7 | 8 |
| Uterine sepsis, | 5 | 5 | 8 |
| Uterine and wound sepsis, | 0 | 0 | 1 |
| Phlebitis, | 0 | 4 | 2 |
| Pneumonia, | 1 | 0 | 0 |

A few words about fetal mortality in Cæsarean section. We have been accustomed to consider

this operation as promising infallibly the birth of a living child, making allowance for an occasional case in which resuscitation falls, and this is certainly true in the primary and secondary sections. In the late section, however, where the fetus as well as the mother has borne the strain of a long and difficult labor, and especially where unsuccessful attempts at delivery have been made, often by practitioners little skilled in obstetric operating, there is a distinct percentage of stillbirths, 5.48 % in the series which I have collected. Adding to these deaths occurring during the first five days of life, the infantile mortality of the late operation rises to 13.28 %, making it a procedure not only dangerous to the mother, but often futile in saving the life of the child. The fetal mortality is shown in the following table.

| Author. | Primary. Cases. | Primary. Stillbirths. | Primary. Deaths. | Secondary. Cases. | Secondary. Stillbirths. | Secondary. Deaths. | Late. Cases. | Late. Stillbirths. | Late. Deaths. |
|---|---|---|---|---|---|---|---|---|---|
| Reynolds,[3] | 82 | 1 | 2 | 158 | 1 | 2 | 49 | 1 | 3 |
| B. L. H., | 75 | 1 | 2 | 37 | 0 | 2 | 32 | 1 | 2 |
| McPherson,[4] | 2 | 0 | 1 | 40 | 0 | 2 | 107 | 13 | 5 |
| Polak,[5] | 4 | 0 | 0 | 4 | 0 | 0 | 6 | 0 | 0 |
| Spalding,[6] | 2 | 0 | 0 | 2 | 0 | 0 | 3 | 0 | 1 |
| Frederick,[7] | 2 | 0 | 0 | 1 | 0 | 0 | 1 | 0 | 0 |
| Kynoch,[8] | 5 | 0 | 0 | 0 | 0 | 0 | 0 | 0 | 0 |
| Reddy,[9] | 0 | 0 | 0 | 2 | 0 | 0 | 3 | 0 | 1 |
| Canton,[10] | 0 | 0 | 0 | 2 | 0 | 0 | 6 | 1 | 0 |
| Wallace,[11] | 9 | 0 | 1 | 4 | 0 | 0 | 3 | 0 | 0 |
| Reid,[12] | 1 | 0 | 1 | 2 | 0 | 0 | 1 | 0 | 0 |
| Mouchotte,[13] | 0 | 0 | 0 | 8 | 0 | 0 | 6 | 0 | 0 |
| Boyd,[14] | 3 | 0 | 0 | 1 | 0 | 0 | 2 | 0 | 0 |
| | 185 | 2 | 7 | 261 | 1 | 6 | 219 | 16 | 12 |

The causes of fetal death in the above series were as follows:

| | Primary. | Secondary. | Late. |
|---|---|---|---|
| Atelectasis, | 2 | 0 | 0 |
| Prematurity, | 0 | 5 | 0 |
| Long labor, | 0 | 0 | 8 |
| Attempts at operative delivery, | 0 | 0 | 4 |
| Congenital heart disease, | 1 | 0 | 0 |
| Spina bifida, meningitis, | 1 | 0 | 0 |
| Unknown, | 3 | 1 | 0 |
| | 7 | 6 | 12 |

Next in importance to prolonged labor and unsuccessful attempts at delivery as a cause of fetal mortality is prematurity. Whenever a Cæsarean baby does not appear especially vigorous, it should be treated as a premature child for the first few weeks. Aside from these conditions, the mortality of children delivered by Cæsarean section is entirely an accidental one.

### CONCLUSIONS.

1. Primary Cæsarean section is a simple and safe operation with a low maternal mortality.

2. The mortality from Cæsarean section increases in direct proportion to the duration of labor, being only 2.7 % in the primary, 5.7 % in the secondary, and 13.7 % in the late operation.

3. Maternal morbidity as well as mortality is increased in the secondary and late Cæsarean sections.

4. While there is no fetal mortality as a result of the operation where the fetus has been previously subjected to the strain of a long and difficult labor, the operation is frequently unsuccessful in saving the life of the child.

5. The maternal mortality of 13.7%, and the percentage of 13.28 of unsuccessful results for the child make the late Cæsarean section an unjustifiable operation.

## THE END RESULTS OF CÆSAREAN SECTION.*

BY NATHANIEL R. MASON, M.D.,

*Assistant in Obstetrics and Gynecology, Harvard University; Physician to Out-Patients, Boston Lying-In Hospital; Third Assistant Visiting Surgeon for Diseases of Women, Boston City Hospital.*

We may divide the end results of Cæsarean section into two classes.

First, those conditions which may occur as a result of the operation.

Second, those complications incident to other methods of delivery which are avoided by it.

Of the latter class we will mention first the absence of perineal and vaginal tears, prolapse and procidentia which frequently follow deliveries per vaginam, especially by means of those operative procedures between which and Cæsarean section the obstetrician is repeatedly called upon to choose. This advantage of Cæsarean section is too obvious to demand further explanation.

Less well recognized but of even greater importance is the absence of nervous collapse, which is far from uncommon as a sequel to labor in the over-civilized woman of to-day. Constitutional ill-equipment for labor was first recognized as an indication for Cæsarean section by Reynolds.[1] His views have been supported by Davis,[2] Newell [3] and others. Reynolds says that when a poorly equipped woman has lost in strength and health during pregnancy, the pains are nearly always poor and irregular, and the uterus acts poorly. Labor is not likely to be spontaneous, and is often followed by a neurasthenic state lasting for a long period.

Those patients of this class upon whom he has performed Cæsarean section have made perfectly satisfactory convalescences and have enjoyed good health during the subsequent year, in marked contrast to the much greater number of those whose labors have been treated by other measures.

The original indication for the performance of Cæsarean section was to secure a living child. To secure a child not only living, but *free from*

* Read by invitation before the New England Hospital Medical Society, Boston, Nov. 17, 1910.

*injury*, should be the object of every obstetrical procedure. The avoidance of fetal morbidity is a greater triumph for Cæsarean section than the saving of fetal life. The cases of hemiplegia idiocy, epilepsy and even of brachial paralysis following difficult intrapelvic operations are the worst results in obstetrics.

A history of difficult or operative delivery was obtained in 29 % of his cases of idiocy by Shuttleworth [4]; 8.9% by Küntzel [5] and 11.6% by Mouser.[6]

Frazier [7] believes that 30 % of all children who recover from cerebral hemorrhage at birth develop epilepsy later in life. Mouser found that 17.64 % of his cases of epilepsy had a history of difficult birth.

It must be remembered, however, that Cæsarean section does not guarantee a child free from injury when the operation has been performed only after a prolonged labor or ineffectual attempts at delivery.

The possible evil results of Cæsarean section may be enumerated as follows: Hernia, uterine fistula, adhesions, rupture of the uterus.

*Hernia.* — It used to be stated that the abdominal wound after Cæsarean section might be closed with through-and-through sutures without danger of hernia, because the relaxed condition of the abdominal wall removed all possibility of strain upon the wound. This statement has proved fallacious. Hernia, although rare, does occur. In 39 repeated Cæsarean sections performed at the Boston Lying-In Hospital, a hernia was found in the former scar of two. In neither of these was the previous operation done at the hospital, so the method of suture is unknown.

*Uterine fistula.* — A fistulous opening into the uterine cavity may develop as the result of infection of the uterine sutures. Haven and Young [8] found 3 such instances among 167 Cæsarean sections collected from the literature. In another such case, reported by Schütte,[9] rupture of the uterus took place in a subsequent pregnancy.

*Adhesions.* — Adhesions are frequent after Cæsarean section, especially between the uterine and abdominal scars, but seldom give rise to trouble. v. Leuwen [10] found adhesions reported in 76 out of 117 repeated Cæsarean sections. They were present in all but 2 of the 39 repeated Cæsareans at the Lying-In Hospital, but not one had any symptoms whatever referable to their presence. In one patient the adhesion between the uterus and abdominal wall was so dense that four Cæsareans were done extraperitoneally, and in one other the fourth operation was performed without opening the peritoneum.

The location of the adhesions found at repeated Cæsarean sections in the cases collected by Haven and Young [8] as well as of those at the Boston Lying-In Hospital is shown in the following table: Gellhorn [11] has reported a case of dystocia following Cæsarean section where the adhesion of the uterus to the abdominal wall caused a depression in the center of the uterus. The fetus was in a transverse position, which could not be corrected by external version, but the patient was successfully delivered of a living child by internal podalic version.

| | Haven and Young. | Boston Lying-in-Hospital. | Total. |
|---|---|---|---|
| Omentum adherent —to uterus, | 16 | 1 | 17 |
| Omentum adherent —to abdominal scar, | 15 | 12 | 27 |
| Omentum adherent —to bowel, | 0 | 1 | 1 |
| Intestine adherent —to uterus, | 4 | 3 | 7 |
| Intestine adherent —to abdominal scar, | 3 | 2 | 5 |
| Uterus adherent to anterior abdominal wall, | 36 | 30 | 66 |
| No adhesions found, | 3 | 2 | 5 |

Adhesions following Cæsarean section do not appear to predispose to miscarriage in subsequent pregnancies. v. Leuwen,[10] in 194 pregnancies following Cæsarean section, found 8 miscarriages, 4.1%; as against 7.5% among 7,718 pregnancies in the clinic of Utrecht during the year 1904.

*Rupture of the uterus.* — The danger of rupture of the uterus in the scar of a former Cæsarean section has been urged as an indication for the routine performance of elective Cæsarean section in subsequent pregnancies. Twenty-one cases of rupture of the uterus during pregnancy or labor in patients upon whom the classical Cæsarean operation had previously been performed are to be found in the literature.[12] In addition to these are twenty instances of thinning of the scar in all or part of its length, which have been collected by v. Leuwen.

Early in the present year, the reader,[12] in conjunction with Dr. Williams, published the report of some experimental work upon the strength of the uterine scar in animals. Our experiments were conducted on cats and guinea-pigs. They consisted of performing Cæsarean section upon these animals as nearly as possible after the methods used in human beings, later removing the uterus and suspending weights to that portion of the uterine muscle containing the scar. It was found in each experiment that the muscle gave way first, and that the scar withheld any strain which could be borne by the uterine wall.

In addition to this experimental evidence of the strength of the uterine scar, we found at the Boston Lying-In Hospital two patients having had previously Cæsarean section who underwent safely normal deliveries,[13] and one other, with a scar due to rupture of the uterus,[14] who passed through the extraction of a breech without untoward results.

In the literature we found 32 cases collected by v. Leuwen [10] of delivery at term through the natural passages after a previous Cæsarean sec-

tion without apparent injury to the uterine scar, and 117 others collected by the same writer who went safely through pregnancy and were again delivered by Cæsarean section.

A careful study of the reported cases of uterine rupture was then made, as a result of which we formulated the following conclusions:

Rupture of a Cæsarean scar is always secondary to unusual weakness of the scar, dependent upon imperfect consolidation.

The most frequent cause of imperfect consolidation is placing the deep stitches too far apart, or not including the entire thickness of the uterine muscle.

Location of the incision and suture of the placental site probably do not affect the strength of the scar.

Infection in certain instances plays a very important part in causing weakness of the cicatrix.

Catgut as a suture material is open to the objection that there is at least a possibility of the stitches becoming untied, and that certainly more cases of rupture have occurred after its use than after the use of silk.

Finally, it seemed to us then and still seems that, given a uterus which has been sutured with care to include the entire thickness of the muscular portion of the wall in each stitch, and to place the deep stitches close together throughout the entire length of the incision, using silk or linen, and where there has been no evidence of sepsis during the convalescence, such a uterus may be subjected with safety to distention by a full-term pregnancy, or even to the strain of labor itself.

*Repeated Cæsarean sections.* — At the Boston Lying-In Hospital there have been performed 39 repeated sections on 26 patients, 2 having had five; 1, four; 5, three; and 18, two. There have been three deaths each after a second section. v. Leuwen [10] gives the mortality in 104 repeated Cæsareans as 3 %. In other words, the mortality is no greater in the repeated operation than in the first, and does not increase with the number of the Cæsarean.

The question has been raised of how frequently a patient may be delivered with safety by Cæsarean section. Of the two patients who had five operations each, in one eleven years, and in the other twelve years and six months elapsed between the first and fifth. Two patients each had two Cæsarean sections within thirteen months. In the entire series the average elapsed time between operations was three years and eight months. It may be safely stated that pregnancies may be permitted as frequently when Cæsarean section is necessary as though the patient were expected to be delivered by the natural passages.

*The justifiability of sterilization after Cæsarean section.* — With the mortality of the repeated operation no greater than of the first, and with the constantly decreasing mortality of elective Cæsarean section, there seems to be little justification for the performance of sterilization. It must always be remembered that the child or children of the patient may die, or she may make a second marriage, under either of which circumstances another pregnancy may be most earnestly desired. The words of Dr. Green [16] on this subject have been widely quoted throughout the civilized world. "If a woman comes to Cæsarean section and recovers, she and her husband, if she has one, should be informed of her condition and of the prognosis and treatment in the event of future pregnancy; if subsequent pregnancy ensues, the responsibility of treatment rests with the obstetric surgeon, but the responsibility for the condition rests elsewhere."

# Reports of Societies.

## ASSOCIATION OF AMERICAN PHYSICIANS.

TWENTY-SIXTH ANNUAL MEETING, HELD AT ATLANTIC CITY, N. J., MAY 9–10, 1911.

THE President, DR. F. FORCHEIMER, Cincinnati, in the chair.

### PRESIDENT'S ADDRESS: THE GENERAL PRACTITIONER.

THE general practitioner is still the backbone of the medical profession. His development implies so much attrition, so much knowledge, so much resourcefulness so much character and so much humanity that when the general practitioner has attained his full growth he is easily among the first citizens of his community. Nowhere does weeding out go on more rapidly than in the medical profession. Those who are eliminated first are the ones who have failed on account of adverse external conditions such as poverty and professional competition. Hartman accepts three kinds of nobility, namely, of birth, of mind and of finance, and places physicians in the second class. Premedical education is in a chaotic condition. According to the higher demands of certain states and certain schools so much time is required for premedical education that the student gets through his medical course at too advanced an age. The remedy for this lies in making a change in the curriculum of the primary and the secondary school.

### A CLINICAL STUDY OF ASCITES.

DR. R. C. CABOT, Boston: Owing to a series of errors which I have made in the diagnosis of ascites, and to minimize the number of mistakes in the future, I have tabulated the autopsy and operation records of the Massachusetts General Hospital for the past forty years. The bulk of the cases are found to be due to one of five causes: Cardiac weakness, nephritis, abdominal neoplasms, cirrhotic liver or tuberculous peritonitis. Among the possible causes of extensive ascites we must not lose sight of the small solid tumors of the ovary. Pleural effusion may be produced by an

extensive ascitic accumulation. This association may lead to a false diagnosis of pleural and peritoneal tuberculosis. The cure of both pleural and peritoneal effusions may result from excising a benign ovarian tumor. Among all causes of ascites, tuberculous peritonitis may sometimes be recognized by the greater slowness of its accumulation of fluid.

DISCUSSION.

DR. LEWIS A. CONNER, New York: Did Dr. Cabot make a study of the fluid itself to aid him in his diagnosis in ascites? It seems to me sometimes that is of considerable value just as it is in pleural fluid.

DR. CABOT, Boston: We worked with the fluids in every case, and I was impressed with the fallibility of this test when one came to really doubtful cases. Of course in cardiac or renal cases one got low gravity fluids, but when one came to tuberculous peritonitis, cirrhosis of the liver and ovarian ascites, the three in which there is real difficulty in diagnosing, at times the characteristic fluid was present but, as a rule, nothing of importance; the albumen and specificity were no guide in these cases.

THE PRESENT STATUS OF THE TUBERCULIN TEST.

DR. LAWRASON BROWN, Saranac, N. Y.: The Von Pirquet and the Calmette test for tuberculosis have greatly extended our use and knowledge of tuberculin. Among laboratory animals only those which are tuberculous react to tuberculin. Normal animals have tuberculin tolerance but no tuberculin anaphylaxis. Many autopsy reports throw grave doubt upon and, personally, I believe disprove all published statistics which go to show that other diseases react specifically to tuberculin. Such cases are in reality double infection. A slight tubercular infection may be sufficient to cause a reaction for a time and yet leave no permanent pathological change visible to the naked eye. The conjunctival test has produced a number of unfortunate accidents, but, by excluding all patients who have ever had trouble with their eyes and using only 1 to 5% solutions of the old tuberculin, the test seems comparatively safe. There is some danger in the cutaneous test, but it is so slight that it may be disregarded except in scrofulous children. The tuberculin test sometimes results positively in healthy men, a circumstance which warns us not to depend too much upon it. Also, failure to react to 10 mgm. of old tuberculin given subcutaneously, does not exclude clinical tuberculosis. However, in the presence of indefinite symptoms these cases do not require treatment. A negative subcutaneous test in a tuberculous person may indicate either the absence of receptors at the site of the lesion or the presence of free antibodies in the blood. If we except, for the time being, leprosy, tuberculin is a specific test for the detection of tuberculous infection. In practice, exposure to infection, characteristic symptoms, such as hemoptysis, pleurisy with effusion or dry pleurisy on both sides, and localized persistent physical signs at one apex are diagnostic data of far more importance in clinical tuberculosis than that derived from the tuberculin tests. The subcutaneous test is still the most reliable of the tuberculin tests.

DISCUSSION.

DR. FREDERICK C. SHATTUCK, Boston: I wish to corroborate Dr. Brown's statement that the subcutaneous test is the most reliable. I have used it for many years with the utmost freedom. I have never seen any untoward result beyond a disturbance of two or three days, except in one case of Addison's disease, that was apparently killed. Two days after injection the patient was dead.

DR. THEODORE C. JANEWAY, New York: I want to corroborate Dr. Shattuck's experience of rapid fatal issue in Addison's disease following injection of tuberculin for diagnostic purpose.

DR. HENRY KOPLIK, New York: I make use of the cutaneous Von Pirquet test in children almost routinely. As you all know, that is the test of preference, but in some cases in older children, wishing to confirm the diagnosis of tuberculosis where there were other conditions present, such as pleurisy with effusion, after the patient had improved and the temperature dropped and the patient has been well for a little while, I have had some very unpleasant experience in trying to confirm the test of Von Pirquet in making injections of old tuberculin. The temperature rose, the effusion increased and the little patients were quite ill. This is a very unpleasant thing to happen to a clinician after his patient has been apparently on the road to recovery.

DR. I. ADLER, New York: I want simply to state that I have had under observation now for two years a case of undoubted Addison's disease, a mild case that has been exclusively and continuously treated with tuberculin injections, beginning with very small doses, and now she is taking very large doses and has been perfectly well and clinically has been bettered by it.

DR. JOSEPH L. MILLER, Chicago: I believe the very conservative stand by Brown is to be very highly commended. Since the introduction of the simpler tuberculin tests, like the Von Pirquet, I believe there has been a great deal of harm and injustice done the patients by assuming that, inasmuch as they gave a positive Von Pirquet, it was necessary that they be sent away from home and treated as patients suffering with a severe form of tuberculosis, whereas, as a matter of fact, there was no clinical evidence that these cases were tuberculous.

DR. BROWN, closing: I would call attention to the fact that the most important group to-day is the masked tuberculosis. Treatment is not necessary in the non-tuberculous, it is not necessary in masked tuberculosis, but it is necessary in the tuberculosis which is either active or quiescent.

THE FAVORABLE INFLUENCE OF QUININE AND UREA HYDROCHLORIDE HYPODERMICALLY IN ACUTE PNEUMONIA.

DR. S. SOLIS-COHEN, Philadelphia: There is a tradition that quinine given early will abort an attack of lobar pneumonia. In an early experience of the writer's 60 gr. of quinine sulphate given in error in a period of six hours, beginning two hours after the initial chill, apparently acted in this manner. The revival of the quinine treatment of pneumonia by Galbraith in 1904 led the writer to employ the double hydrochloride of quinine and urea, with which he has had such favorable experience in the treatment of malaria. From 6 to 10 gm. according to effect, are given in from forty-eight to seventy-two hours. Cinchonism does not develop. Temperature and pulse fall gradually and proportionately, and respiration more rapidly, with a tendency to restoration of the normal pulse-respiration ratio. Blood-pressure remains stationary or increases; cough diminishes; breathing becomes relatively easy; delerium abates or disappears. Crisis does not occur. Termination is by lysis at about the ordinary time, five to eleven days.

Percussion and auscultation signs are uninfluenced. Involvement of new areas may take place during treatment, with return of symptoms, necessitating new injections. Pneumococcic empyema has occurred. The pathologic processes in the lung would thus appear

to evolve in the customary manner, unmodified by the treatment— which is apparently not germicidal and is without effect on tissue changes, but is chemical and antitoxic. Fresh air, water, saline infusions and symptomatic medication when needed were associated with the quinine treatment.

DISCUSSION.

Dr. F. P. Henry, Philadelphia: Two years prior to the time at which Dr. Cohen claims to have instituted the use of quinine in the treatment of pneumonia I was led to its use through an article by Petzold. I used the hydro-chloro-sulphate of quinine. I can corroborate all that Dr. Cohen says in favor of the method.

Dr. A. Jacobi, New York: I have used the double hydrochloride of quinine and urea a great deal, but have found that it frequently produced gangrene of the skin.

Dr. Cohen, closing: I am very glad to hear of Dr. Henry's favorable experience and shall take pleasure in the publication of my paper to give him credit for the priority which he deserves. In my early experience with the double salt of quinine in malaria sloughs and abscesses and failure to absorb were frequently encountered, but, under improved technic, these unfavorable results have been avoided. The skin must be painted with tincture of iodine, injection made deeply, and, in withdrawing the needle, not a drop must be allowed to fall upon the surface.

A PNEUMATOGRAPHIC STUDY OF THE RESPIRATORY IRREGULARITIES IN MENINGITIS.

Dr. Lewis A. Conner and Dr. Ralph G. Stillman: Forty-one cases of meningitis were studied graphically by means of the Marcy spinal-spring type of pneumatograph, one tube being placed about the upper part of the chest to record the thoracic movements and a second about the abdomen at a point midway between the ensiform cartilage and the umbilicus to register the movements of the diaphragm. In 30 cases of tuberculous meningitis respiratory disturbances occurred during some part of the illness and usually throughout the greater part of it. Among 11 non-tuberculous cases alterations in the respiratory rhythm were observed in all but 2 cases. The disturbances of respiratory rhythm in meningitis can be divided into three fairly distinct groups: (1) Type of Cheyne-Stokes; (2) Biot's "meningitic rhythm"; (3) an undulatory type. The Cheyne-Stokes type seen in infants and children with meningitis shows certain differences from that ordinarily seen in adults. Biot's type of breathing is characterized by constant irregularities in rate and force, by frequent occurrence of deep sighs, and by apneic pauses varying in length and occurring at irregular intervals. In the undulatory type there is a rhythmical variation in the force of the respirations, or in the tone of the respiratory muscles, or in both of these together without any periods of apnea. This undulatory type was observed at some time in almost every case. In 12 out of 41 cases it was the only type of disturbance noticed. In 23 cases (56%) Cheyne-Stokes breathing was observed. In 10 cases (25%) Biot's type was noticed at some time. In 6 cases both the Cheyne-Stokes and the Biot types were seen at different times. Because of its occurrence in almost every case of meningitis, and because it is often observed early in the disease, this symptom of disturbed respiratory rhythm is of very considerable diagnostic importance, especially in meningitis of the tuberculous type in which the onset is often slow and insidious.

DISCUSSION.

Henry Sewall, Denver, Colo.: Are you sure enough of your apparatus to consider it quantitatively reliable?

Dr. S. J. Meltzer, New York: Was there any difference between the diaphragmatic and abdominal breathing?

Dr. J. H. Musser, Philadelphia: Were there any controls in the experiments of breathing in children? We all know the remarkable tricks they play with their breathing apparatus when asleep and awake also.

Dr. Connor, closing: In answer to Dr. Sewall, I would say that while, of course, all these instruments are not sufficiently accurate to make them mathematically so, and we can't say we have measured them mathematically, nevertheless, they are very accurate in a general way. They show in case after case the same thing. By heightening or lessening the tension of the pneumatograph we can make some difference. By relaxing sufficiently one can understand that we could get no abdominal tracing at all, but when one gets familiar with the tension to be used, one can get in the same case at different times and under different conditions usually just about the same sized tracing. We used a great many controls in our work with children.

ABDOMINAL TENDERNESS WITH PAIN DUE TO THORACIC LESIONS.

Dr. Arthur R. Edwards, Chicago: I report two cases of severe, diffuse abdominal symptoms in pneumonia and in pericarditis, which completely simulated abdominal perforation or peritonitis, and in which operation disclosed no peritoneal lesion. In neither case was there the slightest symptom or sign or thoracic disease at the time of invasion. The pain was severe, early and diffuse; the tenderness was as marked on deep as on superficial palpation; and the abdominal rigidity was extreme. The usually available differential points were not helpful; the general symptoms, as severe toxemia, high fever, etc., which generally indicate a systemic infection rather than a local condition, were absent. In this thoracic pseudo-peritonitis or pseudo-perforative symptom-complex, the abdominal muscles may be spastic, the legs drawn up, the body rigid, and collapse may intervene. The invasion symptoms indicate operation, and no certain criterion exists at the onset. The majority of operated cases recover.

DISCUSSION.

Dr. J. P. C. Griffith, Philadelphia: Long ago, in 1896, in the first case I saw of this character, I slipped up on the diagnosis and since then I have continued to slip up. It has been my fortune to see a good many of these cases. I have reported five cases and have one unreported case. I agree entirely with Dr. Edwards that the diagnostic signs are not to be depended upon. I have seen cases which I had no doubt were pelvic, but they turned out thoracic. The only thing to do is to make pretty sure before doing operation.

Dr. F. P. Kinnicutt, New York: I think that Dr. Edwards has drawn attention to an important fact that we should all consider. We are all familiar with the mistakes of our surgical colleagues in cases of this kind. If we can wait, if the surgeon is not too insistent for immediate operation, we may obtain some information from examination of the blood. But often the symptoms are so impressive that the surgeon says it is necessary to operate at once.

Dr. H. U. Williams, Buffalo, N. Y.: In this connection I would like to suggest the importance of fluoroscopic examination of the chest, because you get signs of pneumonia which are perfectly evident with the fluoroscope before you get any physical signs.

DR. M. H. FUSSELL, Philadelphia: I suppose there is no one who believes more thoroughly than I in the grave importance, the absolute necessity, of an early operation in abdominal cases of the character simulated by all these cases of Dr. Edwards, and yet I never approach a case which appears to be abdominal without the greatest trepidation because of the mistakes I have made myself, and because of the mistakes I know others have made. There is no one symptom or set of symptoms which will enable us to make a diagnosis; it is the ensemble by which we come to our conclusion.

DR. JAMES TYSON, Philadelphia: I wish to come to the defense of the surgeon under the circumstances. In my early experiences it was the surgeon who suggusted delay, because of the well-known occurrence of such symptoms when there was no necessity for operation. Most of these cases occurred in children. Operation was deferred and the child apparently recovered, but some months later the child was operated on for appendicitis, and appendicitis was found, so that you can have the rule working both ways.

DR. A. JACOBI, New York: The surface abdominal pain is easily explained in such cases by the extensive connection of the pneumogastric nerve. Is there an anatomical connection which explains the intense visceral pain dependent upon thoracic diseases?

DR. J. A. CAPPS, Chicago: I would like to ask Dr. Edwards whether he found any sign of involvement of the diaphragm? I think there is evidence that the diaphragmatic pleura in these cases is involved.

DR. S. J. MELTZER, New York: I have seen a man dying of angina pectoris who had been treated by one of the best men in New York for gastric catarrh and gallstones. I have seen one patient who had been operated on when he had pneumonia which it did not take a very careful examination to discover, and he was in the hands of an excellent surgeon.

DR. HENRY SEWALL, Denver: Is abdominal pain ever noticed when the lesion is in the left lung?

DR. S. SOLIS-COHEN, Philadelphia: I wish to call attention to a case of pneumonia of the left lower lobe which had been mistaken for gastric ulcer because of vomiting of blood-streaked mucus, together with epigastric pain and tenderness. I first saw the patient after three days' illness and at this time there was no doubt of the diagnosis of pneumonia. Recently I have had three cases of pneumonia referred from the surgical to the medical ward, the patients having been sent to the surgical ward with the diagnosis of abdominal disease. The correct diagnosis of pneumonia was there made by the surgeons and the patients transferred.

DR. E. LIBMAN, New York: I would be in favor of having a fluoroscopic examination made before proceeding to operation in these doubtful cases.

DR. J. C. WILSON, Philadelphia: It must be borne in mind that the early signs of croupous pneumonia consist in impaired vesicular murmur and slightly tympanitic percussion resonance.

DR. EDWARDS, closing: In answer to Dr. Sewall's question, there was no diaphragmatic sign. Abdominal pain may be caused by lower lobe pneumonia on either side.

### CONJUGAL TABES DORSALIS.

DR. A. A. ESHNER, Philadelphia: Sometimes several members of a family develop tabes or paresis, sometimes husband and wife, sometimes in addition a second husband or wife, sometimes one or both parents together with one or more children. The association is not common, although probably more so than is apparent. When husband and wife suffer, the former generally is attacked first, the latter subsequently. A moderate number of cases have been recorded in the literature. I report two cases of conjugal tabes. In one the symptoms appeared in husband and wife at about the same time. No history of syphilis was elicited, although infection may have occurred. In the second case it was learned incidentally that the husband of a woman who was under treatment for tabes likewise presented symptoms of the same disease, although he insisted that there was nothing wrong with him and declined treatment; he gave a history of an initial lesion.

### ACUTE DILATATION OF THE STOMACH IN PNEUMONIA.

DR. M. H. FUSSELL, Philadelphia: Acute dilatation of the stomach is a real complication or sequel to pneumonia fraught with great danger to the patient, usually easily relieved and generally unrecognized. I have failed to find in any book an article which speaks of this syndrome in pneumonia. I have met with four typical cases, three within the last year, and one ill-defined case which forces me to believe that I, in common with others, have heretofore mistaken this condition for something else. I report in detail five cases of my own and refer to six cases from the literature, making eleven cases so far reported. In cases which have come to autopsy there has been found constriction of the duodenum at the root of the mesentery. The question as to which is primary, the duodenal obstruction or the dilated stomach, is still undecided. I believe that in these penumonia cases there is an involvement of the innervation leading to dilatation, this dilatation in itself causing by traction a constriction of the duodenum. Unquestionably there are some cases with chronic dilatation which develop acute symptoms, but they are in marked minority. When one has met and recognized a case of acute dilatation, he is not apt to be misled by any case which occurs. The symptoms and physical signs are vomiting, abdominal pain, distention due to enlarged stomach, constipation, collapse, splashing sounds, and peristaltic movement over the stomach. Before the patient is moribund, often before a definite diagnosis has been made, and as a diagnostic step, a stomach tube must be inserted and lavage practiced. This brings great relief and, if dilatation has occurred after the crisis, recovery is almost certain to occur. Lavage must be done as often as distention occurs. When the patient is in collapse it is feared that passage of the tube may be fatal. This is a mistake, for the tube is easily passed and relief is marked. By turning the patient upon his side or abdomen the constriction of the duodenum is relieved. Food and drink must be interdicted. Strychnia and eserin are of value.

### DISCUSSION.

DR. C. G. STOCKTON, Buffalo: The most striking case that I have ever seen occur was one of acute dilatation in a child of nine years. The size of the stomach was unbelievable. It was undoubtedly acute. I think that dilatation does occur in pneumonia more than we realize. I have seen it in two other cases of pneumonia.

DR. C. N. B. CAMAC, New York: It has been suggested, and some of the autopsies tend to support that idea, that the dilatation may possibly be brought on by involvement of one or the other vagus, by mediastinal exudate associated with pneumonia. In some of the cases there was at autopsy very extensive dilatation. It was almost altogether in lower lobe pneumonia.

DR. S. J. MELTZER, New York: Pneumonia produces very often a dyspnea and very often frequent swallowing without any saliva. It is possible that the presence of air thus swallowed may be a factor in the production of dilatation.

### COMPARATIVE TOXICITY OF VARIOUS ALCOHOLIC BEVERAGES.

Dr. Julius Friedenwald, Baltimore, Md.: The plan followed was that of intravenous injection introduced by Daremberg. Rabbits weighing 2 kg. were utilized; the injections were made in the ear veins. Various brands of whisky, brandy and other alcoholic beverages were utilized. It was demonstrated that pure alcohol is less toxic than inferior whisky, and good whisky less toxic than inferior whisky, but more toxic than pure alcohol. Brandy was observed to be more toxic than alcohol or whisky, and genuine brandy just as toxic as ordinary brandy. Rum was shown to be more toxic than alcohol, whisky or brandy, and gin more toxic than pure alcohol. Liqueurs are more toxic than pure alcohol, whisky or brandy, and just as toxic as rum. Beer is but slightly more toxic than pure alcohol, and ale is no more toxic than beer, but more toxic than pure alcohol. Wine is more toxic than alcohol or whisky, and red wines are more toxic than white wines.

#### DISCUSSION.

Dr. G. M. Kober, Washington, D. C.: Did Dr. Friedenwald estimate the amount of fusel oil present before injecting? My impression is that whenever the amount of fusel oil exceeds 1 part to 1,000 it is toxic.

Dr. Victor C. Vaughan, Ann Arbor, Mich.: I would like to express my admiration for Dr. Friedenwald's paper, but I am afraid wrong conclusions will be drawn from it. Because a substance proves poisonous when introduced intravenously does not say that it will prove poisonous when given by the stomach. I do not think his investigations have taken into account this relative toxicity.

Dr. Fiedenwald, closing: I did not estimate the amount of fusel oil before the injection. It is difficult of course to draw any conclusion from a small number of experiments of this kind. This was a little bit of work done by experiments on rabbits to determine the pathological effect of alcohol on rabbits.

### CONCERNING THE CONTROL OF EPIDEMIC POLIOMYELITIS.

Dr. Simon Flexner and Dr. Paul F. Clark, New York: We are confronted in this country with the danger of another epidemic and possibly of repeated epidemics of poliomyelitis, toward which possibility the medical profession will need to be forearmed. The rapid growth in knowledge concerning this disease within a year or two, since and because of its successful transmission to animals, provides a basis for carrying out efforts at prevention of the malady, and affords an outlook in respect to an efficient mode of treatment. At present the chief reliance must be placed upon preventive methods, and these are to be based upon accurate knowledge now available and not deferred until more knowledge may be secured. It should be accepted as a fact that epidemic poliomyelitis is a contagious infectious disease, the cause of which can enter the brain and spinal cord by way of the nasopharyngeal mucosa and can, also, be eliminated from the nervous system by this membrane. Attention should be directed toward proper isolation of cases of epidemic poliomyelitis, to the disinfection of the nasal and buccal secretions, to the proper supervision of nurses and other healthy persons coming in contact with the ill, since such persons have been shown to be carriers of the infection, and to the recognition and control of the slight and abortive cases of the malady from which further extension may be feared. That insects may be passive carriers of the infectious agent we have recently proved in respect to contaminated flies. That an antiserum for the virus of poliomyelitis can be secured is now established, but thus far no antiserum has been prepared that is suitable for therapeutic use. Whether or not one will be produced in the future cannot be foretold. The quest, however, is not particularly encouraging at the moment. On the other hand, we have ascertained that the drug hexamethylene tetramin, or urotropin, possess a certain power of neutralization of the virus of poliomyelitis in monkeys, and we have further discovered that this power can be enhanced by chemical modification of this drug. Whether the problem of the treatment of the disease is to be solved along this line of investigation cannot, of course, be predicted, but the outlook is distinctly hopeful.

#### DISCUSSION.

Dr. L. A. Connor, New York: Dr. Flexner, have you any suggestions to make as to the preventive management of the nasophryngeal mucous membrane?

Dr. Flexner: I have assumed that the disease ought to be dealt with now in the manner with which we deal with epidemic cerebrospinal meningitis. We know a number of simple substances which are aseptic disinfectants for the virus. A very good one is menthol. I think it is a virus which is sufficiently readily injured by means of disinfectants, which are mild enough to be employed. If you consider it a proper and safe measure to use disinfectant solutions in atomizers it could be carried out in that way. We have great faith in cleanliness of the nose, of the hands, of the clothes. I mean by that to keep them free from the secretion. The virus has never been found in the secretions of the nose of human beings, but the number of observations is very small. It is extremely difficult to get secretions from the human nose. We have had the best specialist in New York come to help us to get the secretion from the nose and failed.

Dr. F. P. Kinnicutt, New York: I would like to know the probability of the disease being contagious. Has Dr. Flexner any particular method of disinfection of clothing? Is it possible for any information to be given us in regard to the mode of using urotropin? If we are going to have more of the disease during the summer, it is rather important that all information in regard to methods should be given us.

Dr. Flexner: I think the problem of disinfection is not peculiar. I think I should deal with it as one deals with any of the fairly highly contagious diseases. The reason I have suppressed the precise information about these compounds is that we have probably thirty of them now under comparison and we are going to choose the best one and it would not be fair to say which that is likely to be now, because we do not know; the point is that it is a possible line of advance.

Dr. M. H. Fussell, Philadelphia: When should we begin to use urotropin?

Dr. Flexner: I do not think you could begin to use urotropin too early.

### TWO CASES OF LEUKEMIA WITH DISEASE OF THE GUMS.

Dr. Henry Jackson, Boston, Mass.: The two cases reported are of especial interest in that the chief symptoms in each case was due to disease localized in the gums. The gums were much thickened, measuring one inch in cross section; along the edge was superficial ulceration, and the gums bled easily when touched. Both cases were considered as some local disturbance of the gums and mouth until the blood examination made the diagnosis possible. The first case is one of acute lymphatic leukemia. As the glands were not enlarged in the first part of the disease this case suggests that the cause of the leukemia is to be sought in the

bone marrow rather than in a disturbed function of the lymphatic glands. This supposition is further substantiated in that though most of the cells were typical large lymphocytes, some of the cells were very similar to myelocytes, as granules were present in the cell substance. The second case was a man thirty-six years of age; a dentist. December, 1910, swelling of submaxillary glands, soon followed by swelling of the cervical glands and gums; gums tender, hemorrhage; chief complaint great weakness. He was admitted to my ward with a diagnosis of scurvy. In this case the first impression of the stained specimen suggested an acute lymphatic leukemia, but the granules showed the cells to be abnormal myelocytes.

DISCUSSION.

DR. R. C. CABOT, Boston: It seems to me we have more difficulties as years go on in a fair demarcation of the clinical picture of acute lymphoid leukemia from the clinical point of view. It has always been an occasional stumbling block that certain cases of whooping-cough have such an enormous number of lymphocytes and there are several instances of supposed leukemias reported recovered which were obviously whooping-cough. There is another difficulty, namely, a septic lymphocytosis.

DR. HENRY KOPLIK, New York: Mention has been made of a condition of lymphocytosis after pertussis. Most men working among children feel that the blood picture in children can scarcely be compared with that of the adult. Anemias in children so closely simulate leukemias in the adult that one must be cautious in speaking of lymphatic leukemia.

A CASE OF SO-CALLED LEUKANEMIA.

DR. W. F. HAMILTON, Montreal: The patient, a farmer, aged forty-three, previously healthy, noticed a mass below the left costal border, which increased in size; he lost appetite, weight and strength and grew pale. Examination showed a spleen which reached down to Poupart's ligament, the liver was 2½ inches below the costal margin in the nipple line. There was no ascites or glandular enlargement. The leucocytes numbered 5,600 and myelocytes were present. The polymorphonuclear cells were diminished while the lymphocytes and large mononuclear cells were greatly increased. The hemoglobin was 65% and the red cells 3,150,000. Death occurred about two and one-half years after onset. No autopsy was made. This case was really one of atypical leukemia. The term leukanemia might well be discarded.

DISCUSSION.

DR. R. C. CABOT, Boston: What were the clinical features of the case aside from the blood?

DR. W. B. JAMES, New York: I wonder how many of the members of the Association feel perfectly satisfied with the recognition of such cases as this and those described as acute lymphatic leukemia as a distinct morbid entity? The term "leukanaemia" implies the ordinary lymphatic leukemia. In the cases of this kind I have seen I have not felt at all sure that the disease I was studying was really of that particular type, that is, of the type of lymphatic leukemia or leukocythemia. Surely the fact that the cases go on to a fatal termination ought not to be used by us in our classification.

DR. HAMILTON: In reply to Dr. Cabot's query, the clinical features were those of weakness, a slight pallor, no fever, moderately increased pulse rate, no edema, an enormously large abdomen and a very greatly enlarged spleen over which one could feel to and fro movements. There was ascites, no pain or tenderness over the long bones. The peripheral lymph glands were not enlarged. The patient was in the hospital for four weeks and subject to x-rays and made little or no improvement.

THE POSSIBLE PREVENTION OF PNEUMOCOCCUS EMPYEMA BY UROTROPIN.

DR. FREDERICK C. SHATTUCK, Boston: The lethal action of urotropin on the typhoid bacillus in urine, the general permeation of the body by this drug and the general delicacy of the pneumococcus, suggested that possibly empyema might be wholly or partly prevented as a sequel of pneumonia by the routine administration of the drug. Thus it has been used for the past year in nearly all the cases of pneumonia in my service in the Massachusetts General Hospital and in some of those of my colleague, Dr. Gannett. The drug was given as the diagnosis was established, in doses of 10 gr., three times a day and continued into convalescence. In 3 out of 59 cases taking urotropin in this manner, empyema developed. During the same period, 46 cases were treated without urotropin, only 1 developing empyema. In the preceding year, of 142 cases of pneumonia without urotropin, 3 developed empyema.

Dr. Barker, kindly complied with my request to try the treatment at the Johns Hopkins. Of 34 cases treated with urotropin, 6 developed empyema. Of 35 cases in the previous year without urotropin, 1 developed empyema. Dr. Kinnicutt also has kindly collaborated at the Presbyterian Hospital in New York. Of 19 pneumonia cases taking urotropin, 1 had empyema. Of 193 without the drug, 5 had empyema. These figures seem to show that this remedy is in no sense a preventive of empyema following pneumonia. It is interesting and may be important to note that neither in the Massachusetts General nor the Presbyterian hospitals did pericarditis develop in any case taking urotropin, although it was noted in 4 to 5% at the Massachusetts and in 1.5% at the Presbyterian in those not taking the drug. Furthermore, the Massachusetts' records show that otitis media occurred in about 4% of the non-urotropin cases, in no instance in the urotropin series.

*(To be continued.)*

## Book Review.

*State Registration for Nurses.* By LOUIE CROFT BOYD, R.N. Philadelphia and London: W. B. Saunders Company. 1911.

This monograph consists of a compilation and comparative summary of the laws governing the registration of nurses in the various states of the Union. These data are presented in several tables, dealing respectively with State Boards of Nurse Examiners, with registration requirements, with fees for registration and their disposition, with exemptions and restrictions, with penalties for violation of the laws, with grounds for revocation of license, and with reciprocity, the recording of certificates and compulsory laws. There is appended an excellent bibliography of the subject, which, with the statistics given, should make this publication of value to all interested in the profession of nursing and its legal status.

THE BOSTON
# Medical and Surgical Journal.

THURSDAY, JUNE 22, 1911

*A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.*

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

*All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 800 Paddock Building, 101 Tremont Street, Boston.*

*All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.*

*Remittance should be made by money order, draft or registered letter payable to*

101 TREMONT STREET, BOSTON, MASS.

## ANNUAL MEETING OF THE MASSACHUSETTS MEDICAL SOCIETY.

THE annual meeting of The Massachusetts Medical Society, held in Boston on June 13 and 14, marked the celebration of the one hundred and thirtieth anniversary of the organization, which is, with the single exception of the New Jersey Medical Society, the oldest association of its kind in the country. The weather on both days of the meeting was delightful. On Tuesday morning, June 13, there were specially arranged clinics at the Massachusetts General Hospital and at the Boston City Hospital, and on the afternoon of this day the Fellows of the Society were invited by the Faculty of Tufts College Medical School to afternoon tea and demonstrations at the school building. At the Harvard Medical School there were exhibits and demonstrations by the several departments. There was also established in the Administration Building an efficient Bureau of Information, for which, and for its ability in managing the complex machinery of the meeting, great credit is due to the committee of arrangements.

The meetings of the several sections were held on June 13 at the Harvard Medical School. At the Councillors' meeting held at noon on Tuesday, Dr. George B. Shattuck, of Boston, was re-elected president of the Society for the ensuing year. Dr. Ernest S. Jack, of Melrose, was elected vice-president; and Dr. Walter L. Burrage, of Boston, Dr. Edward M. Buckingham, of Boston, and Dr. Edwin H. Brigham, of Brookline, were re-elected secretary, treasurer and librarian, respectively.

In the evening of June 13, at the Boston Medical Library, Dr. Richard C. Cabot, of Boston, delivered the annual Shattuck Lecture, under the title "Observations Regarding the Relative Frequency of the Different Diseases Prevalent in Boston and Vicinity." He spoke particularly of the relation of alcoholism to other diseases, and defined certain standards of intemperance and of temperance in the use of alcohol and of tobacco.

On Wednesday morning, June 14, was held the annual meeting of the Society. At noon the Annual Discourse was delivered by Dr. Maurice H. Richardson, of Boston, who emphasized the diagnostic value and therapeutic importance of early exploratory laparotomy, particularly in obscure conditions in the epigastric and right hypochondriac regions. This Discourse, the Shattuck Lecture, and the several papers, together with a full report of the proceedings and of the discussions at the section meetings, will be published in later issues of the JOURNAL.

The annual dinner of the Society, at Symphony Hall, was attractively served and was attended by over 1,160 members. During its progress there was most excellent singing by the Doctors' Chorus, which received deservedly hearty applause. Dr. George B. Shattuck presided at the dinner, and introduced the speakers. Governor Foss spoke of the peculiar opportunities of the medical profession for public service, and of the particular present necessity for such service as only physicians can render. The Rev. Mr. E. H. Rousmanière emphasized the importance of reserve power in the practise of medicine, and declared that the good physician, even more than the clergyman, should live in the realization of the invisible, in the faith which is "the substance of things hoped for, the evidence of things not seen." Mr. Arthur D. Hill commented pleasantly on the relations of the medical and of the legal professions, and explained their fundamental unity of purpose as a common effort for the determination of truth.

Following the adjournment from dinner the Annual Outing of the Society was held on the grounds of the Chestnut Hill Golf Club. Baseball games had been arranged between teams representing the different districts, and a number of exciting games were played and were equally enjoyed by participants and by spectators. The cup was won by the nine representing the Norfolk District Society.

Contrasted with larger assemblies, such as those of the American or of the British Medical Association, the meeting of the Massachusetts Medical Society does not suffer by the comparison. For it represents, on an even more intimate though on

a smaller scale, the close personal fellowship of the members of our profession, their unity of purpose and interests, their common zeal in a great cause. The warmth of this association was well evidenced by the recent meeting, to which was added the further interest of a notable anniversary in the history of an organization whose honorable years cause it to deserve and to receive from its members an ever increasing loyalty.

## THE WESSON MATERNITY HOSPITAL.

THE Wesson Maternity Hospital, at Springfield, Mass., is unique in this state as a lying-in hospital, equipped with the best of modern appliances, to which any reputable physician may send his private patients and where he may attend them with all the advantages and conveniences of such an institution. The importance of such surroundings to both patient and physician can hardly be over-estimated or over-emphasized. The hospital was built, furnished and equipped with a bequest of two hundred thousand dollars from Daniel Baird Wesson, of which some six thousand dollars remained with all obligations paid. Mr. Wesson also provided an endowment of two hundred thousand dollars. The late Mr. Bertrand E. Taylor, of Boston, was the architect. The work was in the hands of a building committee, all physicians but one.

The buildings occupy three sides of a quadrangle. The Maternity is entirely of stone, brick, iron, concrete and terraza with no wood except doors, which have plain surface of polished wood with no panels. The floors are laid on concrete arches. There are no door or window casings, simply the frames, which are flush with the plastering, as are the covered baseboards.

The walls are oil painted, with a dull finish, except in the delivery and operating rooms, where they are white enamel above the marble sides. The heating is all from stack rooms in the basement with fresh-air supply under control. The ventilating is by the suction method, high-pressure steam stacks being in compartments above the roof which connect with every room, corridor and toilet. Each room has a bath and toilet not opening directly, but by a connecting corridor. A number of rooms have private balconies and the main corridor on each floor terminates in a large sun room. There is a solarium on the roof, thirty by fifty feet, half enclosed by glass and half open under an awning. Every room has a telephone connection with every part of the hospital and also with the outside public service. A large electric elevator runs from basement to roof. Each floor has a diet kitchen with steam and gas heaters, refrigerator and water filter. Each floor also has its own nursery.

The large and well-equipped operating and delivery rooms are on the third floor, and, with the sterilizing room and physicians' lounging, bath and dressing rooms, are cut off from the rest of the floor. All the furniture and fixtures are of special design and selection, of fine material and finish, but with plain surfaces with no dust-catching ornamentation.

The domestic building has in the basement the boiler room which furnishes the high and low pressure steam and hot water. A private electric lighting plant is now being installed. The first floor is occupied by the kitchen and refrigerators. On the second floor is the laundry fully equipped and the machinery all run by electric motors. The third floor contains servants' sleeping rooms.

The Nurses' Home forms the third side of the quadrangle and contains a parlor, dining room for nurses, a private dining room for superintendent and physicians, a lecture hall and sleeping rooms, mostly single. The buildings are all connected by a two-story corridor with an open deck above. The location, while near the center of the city, is on high ground and so situated as to give abundant air and sunshine.

The hospital has no staff, each patient employing and paying her own physician. There is a provision whereby a physician may enter a case in the wards free of charge, but must also assume her care without fee. The prices charged are from twelve to fifteen dollars a week in the several wards and from twenty to thirty-five dollars a week for private rooms. The income from patients is such that only a part of the endowmeat income is required to meet expenses.

The hospital was opened to receive patients on Dec. 1, 1908, and the first case was admitted on the following day. On June 13, 1911, the thousandth delivery in the hospital took place. Of the babies born there, there have thus far been nine cases of twins and one case of triplets. A recent item in the Springfield *Daily Republican* gives the following additional information in regard to the training school:

"The hospital has lately bought and refitted the cottage at the corner of Hugh and Myrtle streets for nurses' rooms, as the nurses' home has long been insufficient.

"The nursing force consists of three head nurses who are permanent and twenty-five or

more nurses who have had at least eighteen months' training in a general hospital and come here for four months' training in maternity work.

"Besides the practical service, they are given a regular course of class work and recitations by the superintendent, lectures by appointed physicians and a final written examination, which, if successful, gives the diploma and a right to wear the hospital badge. The nurses at present come from the Springfield Hospital, Wesson Memorial Hospital, Massachusetts General Hospital and Bridgeport Hospital Training Schools. The Boston City Hospital and several others in New England have made formal application that their nurses be received for training."

The Wesson Maternity Hospital, therefore, has an educational function in the community. But not only does it train nurses in the care of obstetric cases; it also and primarily affords to patients of moderate as well as to those of comfortable means an opportunity to obtain at actual cost the conveniences and advantages of the most modern hospital environment. It is in this respect a model of a type of institution of which more are needed in this community.

## THE CELEBRATION AND SEQUELÆ OF PATRIOTIC HOLIDAYS.

During the local celebration, last week, of Bunker Hill Day, 25 persons were injured, more or less seriously, by explosives, as compared with 8 who were injured in the similar celebration a year ago; and there were in Boston 23 bell alarms for fire, as compared with 14 last year. These figures of unnecessary trauma and destruction of property indicate not an advance in rational methods of popular celebration, but a discreditable reversion to more barbaric customs.

In recent years there has been a growing agitation for more sensible observance of such patriotic holidays. The annual tale of conflagrations, gunshot wounds, and tetanus has gradually impressed many people with a realization of its really criminal wastefulness. Numerous statistics on this subject have been published. At the present, suffice it to recall that in the seven years from 1903 to 1909, inclusive, the total number of persons (chiefly children) reported to have been injured in the celebration of Independence Day in the United States was 34,603. Of these, 1,531 died of their injuries, an average of 219 a year. The total number of American soldiers who died of trauma in the war with Spain was 336. These figures represent the annual sacrifice made to injudicious patriotic enthusiasm, a sacrifice precisely analogous to that made to typhoid fever and other preventable diseases.

Last year it seemed that considerable progress had been made in the reduction of this needless destruction of life and property. In seventeen of the largest cities of the country there was in 1910 a reduction of over 65% in the number of casualties from those reported in 1907. It is to be hoped that the recent record of Bunker Hill Day is not an evidence of backsliding in this respect, and that the celebration of the coming Fourth of July will show increasing sanity and self-control on the part of the American people.

Numerous papers and periodicals this year have joined in advocating more rational methods of celebration. The Russell Sage Foundation has sent to over one thousand cities literature giving statistics of Fourth-of-July injuries and suggesting a sensible program of observance. The Journal which has from year to year published editorials on the subject at this season, now re-emphasizes its attitude and calls the attention of physicians to their duty and possible power in promoting the reform. Moreover, it would urge not only prevention of injuries, but the use of the most efficient methods in their treatment. One of the most fatal elements in Fourth-of-July trauma is tetanus occurring as a sequela of blank-cartridge wounds. The marked reduction in the mortality of this disease has followed the more general prophylactic employment of antitetanic serum in conjunction with radical surgical exposure and cleanliness of the wound. The value and importance of this mode of procedure seem established. We wish particularly to recommend its adoption by every physician who has occasion to treat such cases during the coming Fourth of July.

## GENIUS, EUGENICS, AND DEGENERACY.

In a recent article in the London *Westminster Gazette*, Mr. J. A. Spender, pointing out some of the possible disadvantages of the new science of eugenics, calls renewed attention to the close and not altogehter discreditable relationship between genius and certain forms of so-called degeneracy.

"Where my eugenic friend goes wrong," he says, "is in failing to realize that a great many of the maladies which he calls degeneracy are just too much of the highly developed nervous system which is the special endowment of the gifted families.

"Overcharge the battery ever so little and genius becomes insanity; give one member of the family a volt too much and the delicate balance of physical and mental qualities on which sanity

depends is broken down. Extinguish the family and you will rid the world of some degenerates, but you will also and at the same time rob it of its most gifted men.

"My eugenist would never have let Cowper, Lamb, Coleridge, Stevenson, Keats, Ruskin, Henley or De Quincey see the light.

"The doctrine of heredity should never be forgotten by parents or remembered by children. To the first it is the assertion of their responsibility; to the second, a reminder of their helplessness."

Doubtless eugenics, completely applied in practise, would tend to eliminate genius and degeneracy. Whether this would be desirable, need not now be considered, for it is hardly conceivable that eugenics can or will ever be so applied. Genius may be defined as a bye-product of evolution. It is to be regarded as an abnormality, not as the perfect type towards which natural process is working. But though it is a form of variation which may prove destructive to the individual or to the family, its repeated occurrence through the ages has proved of immense value and service to humanity. The types that have perished have done their share in human advancement as well as those that have survived and are destined to persist and endure. Genius is prophetic as degeneracy is reversive. Both are cognate collateral experiments from the great laboratory of life.

## A BRITISH COMPLIMENT TO BOSTON.

AN editorial on "Medical Letter-Writing," in the issue of the *Lancet* for May 6, describes a work recently published by Dr. Joseph Collins, of New York, entitled "Letters to a Neurologist." This work consists of a series of communications, supposed to be addressed by patients to their physician, and of his answers thereto. It is an extension of the epistolary mode of treatment for nervous diseases advocated some years ago by Oppenheim, of Berlin, in his "Letters on Psychotherapeutics."

The reviewer in the *Lancet* evidently considers Dr. Collins's style at times a bit technical, for he says: "We presume that the audience to which the 'Letters' are meant to appeal is a medical audience, for some of the replies to patients are couched in language that must be, we should think, obscure to the public, *even in Boston*. 'We physicians speak of migraine as a nervous disorder of degeneracy or deviation. By thus designating it, we endeavor to indicate that it occurs in individuals whose evolutionary development has not been sufficiently harmonious to allow the different components of the finished product so to work in unison that the result is a symphony, emotional, intellectual, or physical.' What consolation this may convey to a particular sufferer, torn with pain, we do not pretend to conjecture."

It is hard to say whether these remarks should be taken rather as a criticism of Dr. Collins or as a tribute to the supposed high level of popular intellectual culture in Boston. Surely the literal and figurative meaning of the term "symphony" should be appreciated in Boston, if nowhere else. We are disposed to accept the *Lancet's* editorial as a compliment, and to remind our distinguished contemporary that in this respect, as in all others,

"Dies erit pregelida
Sinistra cum Bostonia."

## MEDICAL NOTES.

PLAGUE AND SMALLPOX AT AMOY. — Press dispatches from Amoy, China, report that during the fortnight ended June 16, there were in that city 7 deaths from smallpox and 83 from bubonic plague.

CORONATION HONOR FOR DR. OSLER. — Among the coronation honors announced at London this week is that of a baronetcy to be conferred on Dr. William Osler, Regius Professor of Medicine at the University of Oxford.

A PROLIFIC FAMILY. — Charles Garnett, who died on June 16, at Garnett Settlement, near St. John, N. B., was said to be the father, by one wife, of twenty-three children, all but two of whom are now living and well.

EXCESS OF WOMEN IN GREAT BRITIAN. — According to the recent British census, the excess of females over males in Great Britain is now 1,178,317. In this enumeration, however, soldiers and sailors abroad are not counted. If the laws governing the determination of sex were definitely understood, the reason might be found for the progressive increase in the proportion of women to men among civilized nations.

PHYSICIANS' FEES IN JAPAN. — An item in the *Orential Review* states that "the strict honesty" of the Japanese people makes it unnecessary for a doctor in Japan to ask payment for his services. "When he has finished his visit, a present is made to him of just as much as the patient can afford." Such a custom, even though it bring small fees, should relieve physicians in that

delectable land not only from the trouble of rendering accounts but also from the liability of suits for overcharging.

A Living Centenarian. — The Rev. William Rankin, who graduated from Williams College in 1831, celebrated, recently, the supposed one hundredth anniversary of his birth. He is said to be the oldest living alumnus of any college in the United States, and the only one who has lived to be a centenarian. College education does not seem to predispose to great longevity.

Three Centenarians. — Mrs. Sarah Ann Blunt, a negress who died last week at Brooklyn, N. Y., was locally reputed to have been born a slave in Maryland on Dec. 25, 1810. She is survived by one granddaughter.

Joseph Mercer, of Cambridge, Mass., died in that city last week at the supposed age of one hundred and one years. He was born in Montreal, P. Q., Canada, but early went to Arichat, Nova Scotia. Later he came to the United States, and had lived successively in Newton and Nonantum, Mass., at Providence, R. I., and at Somerville and Cambridge, Mass. He never smoked tobacco or drank alcoholic beverages, and to this abstinence ascribed his longevity and success in life. He is survived by his widow, by two sons, and by two daughters.

Mrs. Mary A. Smith, of West Poland, near Lewiston, Me., died last week, at the alleged age of one hundred and two years, in the same house where she was born and had always resided. She was said never to have seen a railroad train. She was a widow and childless. She had been a paralytic invalid for several years prior to her death.

Fines for Food Adulteration in Switzerland. — Fines for adulteration of foodstuffs vary widely in different communities, according to their financial status and local attitude towards the importance of pure food. A recent Swiss publication gives the following description of fines imposed in various districts of Switzerland:

"In one town the punishment for selling milk to which water has been added may be as high as $40 fine in addition to five months in prison. At another town, for the same negligence, in an instance in which the amount of extension was 5 or 6 per cent, the fine was $7.50 with an additional $3.75 for the costs of the analysis, which fell to the loser in the trial, and for unclean receptacles for sugar and other foods, forty cents. At Lausanne an unclean beer pump costs its owner $1 and twice as much for the tests of its cleanliness; the sale of wine sweetened with sugar is set down at $1; artificial wine for natural, $2; while 'moistened' wine, the moistening medium being water, may result in a fine of $2, and various debasements of the purity of brandy and cordials cost from $1 to $5, according to the seriousness of the offence. At Cossonay the magistrate records a fine of $2 against a dealer who permitted his cognac 'to become altered in specific gravity,' while at Nyon the sale of absinthe means $20 to $30 fine; the mere possession of foreign artificial wine, $2, which is likewise the penalty for false indication of the locality of imported wine."

## BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, June 6, 1911, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 85, scarlatina 26, typhoid fever 9, measles 156, smallpox 0, tuberculosis 76.

The death-rate of the reported deaths for the week ending June 6, 1911, was 15.97.

Boston Mortality Statistics. — The total number of deaths reported to the Board of Health for the week ending Saturday, noon, June 17, 1911, was 208, against 196 the corresponding week of last year, showing an increase of 12 deaths, and making the death-rate for the week, 15.74. Of this number 104 were males and 104 were females; 199 were white and 9 colored; 133 were born in the United States, 72 in foreign countries and 3 unknown; 49 were of American parentage, 131 of foreign parentage and 28 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 50 cases and 2 deaths; scarlatina, 42 cases and 3 deaths; typhoid fever, 9 cases and 0 deaths; measles, 97 cases and 2 deaths; tuberculosis, 61 cases and 18 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 27, whooping cough 2, heart disease 26, bronchitis 0. There were 14 deaths from violent causes. The number of children who died under one year was 31; the number under five years, 51. The number of persons who died over sixty years of age was 69. The deaths in hospitals and public institutions were 86.

Meeting of Tufts Medical School Alumni. — The second annual meeting of the Tufts Medical School Alumni Club was held in Boston on June 13. Addresses were made by the Rev. Frederick W. Hamilton, LL.D., president of Tufts College, by Dr. Harold Williams, and by Dr. Frederic M. Briggs.

GRADUATION OF NURSES AT EVERETT. — The annual graduation exercises of the Whidden Memorial Hospital Nurses' Training School at Everett, Mass., were held in that town last week. Two pupil candidates received diplomas.

APPOINTMENT TO MASSACHUSETTS STATE BOARD OF HEALTH. — It was announced last week that the Governor has appointed C. Eugene McGillicuddy, of Worcester, Mass., as a member of the State Board of Health, in the place of the late Gerard C. Toby.

BEQUEST FOR A SCHOLARSHIP AT THE HARVARD MEDICAL SCHOOL. — The will of the late Frank Dunlop Frisbee, who died in Newton, Mass., on May 16, was filed last week at the Probate Court, East Cambridge, Mass. It contains a bequest making provision for the foundation at the Harvard Medical School of a scholarship, to be known as the Jesse F. Frisbee Scholarship, "to aid any poor but deserving student." One-sixth of the residue of the estate is given for the support of this endowment.

MILK AND OPIUM FINES IN BOSTON. — Before the Boston Municipal Court last week, fines amounting to a total of $160 were imposed on 12 dealers of this city for having in their possession milk that was below the standard required by law. Before the same court another dealer was fined $10 for having in his possession 12 ounces of opium. Several "drug dens" have been raided in this city during the past week, and a number of arrests made. The husband of a prisoner in the House of Detention was last week detected in the act of conveying morphine and cocaine to his wife while visiting her, and for this offense was fined $100.

HARVARD MEDICAL ALUMNI ASSOCIATION. — It is announced that by vote of the Council, the annual business meeting of the Harvard Medical Alumni Association will be held on Commencement Day, June 28, in Harvard 1 in the College Yard, Cambridge, at 12.30 P.M., immediately after the exercises in Sanders Theatre. The Spread will be held afterwards in Stoughton 1 and 2, as usual.

Members of the graduating class of 1911 of the Medical School are cordially invited to be the guests of the Association at the Spread and to make these rooms their headquarters on Commencement Day.

NEW YORK.

TWO GIFTS TO HOSPITALS. — Lispenard Stewart of New York, has made a gift of $25,000 to Roosevelt Hospital and given a similar amount to the New York Eye and Ear Infirmary, of whose board of directors he has for several years been president.

CORNELL MEDICAL COLLEGE COMMENCEMENT. — The thirteenth annual commencement of Cornell University Medical College was held on June 14, when there were fifty-three graduates, of whom eight were women. The resignation was announced of Dr. Rudolph A. Wittaus as professor of chemistry, toxicology and medical jurisprudence, a position which he had previously held in the medical school of New York University. Professor Wittaus was one of the founders of the Cornell Medical College and a member of its governing council, and he was presented by the faculty with a set of resolutions in grateful acknowledgement of his years of distinguished service in the institution and expressing regret at his retirement. He has now been made professor emeritus.

VITAL STATISTICS OF 1911 IN NEW YORK CITY. — In the quarterly report of the New York City Health Department, issued on June 14, a more favorable showing is made. While the actual number of deaths increased, as compared with the corresponding quarter of 1910, on account of the increase of population, there was a decline in the death-rate. The number of deaths reported in the first three months of 1911 was 20,876, as against 20,660 last year, but the death-rate was 17, as against 17.45. From the average rate of the corresponding quarter of the last five years, which was 18.33, there was a much more marked decrease. The number of births reported during the quarter was 34,506, an increase of 1,901 over 1910.

EARLY OUTBREAK OF CHOLERA. — Cholera has made its appearance early this season. During the voyage of the Italian Line steamship *Europa*, from Genoa and Naples, which arrived at quarantine on June 14, one of the steerage passengers had an attack of the disease, and was recovering by the time the ship reached port. The North German Llyod liner *Berlin*, which arrived the day previous from Naples, reported that four days after sailing a steerage passenger was seized with it and died thirty hours later. The ship's surgeon, Dr. Kliemann, and Dr. Sterzi Ippolito, the Royal Italian Health Commissioner, who was on the *Berlin*, agreed as to the diagnosis of Asiatic cholera, and later this was confirmed by bacteriologic tests; as was also the case with the *Europa's* passenger.

Hospital Fire Discipline. — The admirable discipline in case of fire which has been established in Bellevue Hospital was well shown recently, when a fire occurred at that institution. It broke out in a drying room on the top floor of a recently constructed pavilion, a six-story building constructed of brick, and the alarm was promptly given by one of the women nurses. Fire drills are held regularly twice a week at Bellevue, and although it required some half hour's effort to conquer the flames completely, the work was accomplished so quietly (the city fire department not being called in) that it is stated that the patients below the fifth floor were unaware that anything unusual was going on. Panic was entirely averted among those in wards nearest the conflagration, while in other wards the windows were closed to prevent the smell of smoke and music boxes were set playing to divert attention.

Mortality Statistics of 1911 in New York State. — In the latest number of the *Monthly Bulletin* of the State Department of Health it is stated that during the first four months of 1911 there were 53,400 deaths in New York State, as against 51,630 in the same period of 1910; the death-rate in each month exceeding that in the corresponding month of last year. In both years March had a mortality never before reached in any month except in March, 1904; the month of March in these three years being the only months in the records of the department in which the number of deaths exceeded 14,000. While in April of this year the decrease in deaths from March was 900, in 1910 this decrease was 1,300; showing that the causes of sickness and death which were so marked in the early months of both years have this season persisted longer into the Spring. In these four months last year influenza was reported as the direct cause of about 1,000 deaths; this year the number is 1,336. Of the diseases in which the mortality is affected by influenza the deaths from pulmonary tuberculosis were increased by 200, from pneumonia, by 400, from other acute respiratory diseases, by 60, from Bright's disease and other affections of the genito-urinary system, by 300, from diseases of the nervous system, by 300, and from diseases of the circulatory system, by over 800. The annual winter epidemic has therefore been one of exceptional severity this season, and, crediting the epidemic, of last season with 10,000 deaths, there is reason to believe that the current one, which began in December and reached its height in March, has thus far added to the mortality no less than 12,000 deaths. Smallpox is reported as having made its appearance in several localities, causing, as usual, a diversity of opinion regarding the diagnosis. A striking instance of the protective value of vaccination is shown at a hotel in the state where the forty regular boarders were recently exposed to the risk of contacting the disease. Thirty-seven of them, who had been successfully vaccinated, escaped infection, while the other three are now down with smallpox in the isolation hospital. The Health Department has just established a traveling library for the benefit of health officers. Believing that many of these officials throughout the state would welcome the privilege of studying some of the most instructive and up-to-date works on subjects relating to their duties as sanitary officers, the department has purchased a number of sets of such books and had them packed in boxes for loaning on request.

7. Kerr, Le G. *A Neglected Phase of the Prevention of Summer Gastro-enteric in Infants.*
8. Greely, H. *A Case of Pulmonary Tuberculosis, with Heart Displaced to Right Side.*

3. Hill sums up the conclusions of Chapin in regard to the epidemiology of diphtheria and reports an epidemic at an army post in New York State, in which his theories were tested. His conclusions agree with Chapin's, that carriers, missed cases and atypical or undiagnosed cases of diphtheria must be considered as of much more importance in the spread of the disease than fomites. House disinfection and quarantining healthy as well as sick inmates of a household is an unscientific method of controlling epidemics if no attention is paid to carriers.

7. Roberts gives Sambon's new theory of the origin of pellagra as follows: "Pellagra is not due to the eating of maize, either sound or deteriorated. A blood-sucking fly, of the genus Simulium is, in all probability, the agent by which pellagra is conveyed." Roberts compares this theory with conditions in Georgia and says: "Georgia and Italy both have pellagra. The two have the same tropographical conditions. Pellagra originates in both territories along streams. Both countries have many Simulium flies."

8. Talbot's excellent article discribes clearly and in detail the method of establishment and the reasons for the success of a directory for wet-nurses. This most excellent and much-needed institution has been established in connection with the Massachusetts Infants' Asylum and a very rigid system of physical examination of the nurses is carried out. The following postal-card explains this scheme: "A directory for wet-nurses has been established at the hospital of the Massachusetts Infants' Asylum, Jamaica Plain. Wet-nurses may be obtained here at any time by paying a fee of ten dollars. The institution is not expected to make money and this fee is a nominal one to help pay expenses. The wet-nurses and their babies are examined physically by a physician; no one will be recommended with any signs of tuberculosis or syphilis. . . . An attempt is made to teach the mothers how to be cleanly, self-respecting and how to care for their babies. The Directory requests you to send to it any woman who desires to obtain a position as wet-nurse; she will be given board and lodgings free if she is a worthy person. In this way she will have an opportunity to remain with her baby and to get work. Further information can be obtained by telephoning the hospital."

9. Flexner and Clark report the following very interesting experiments on the question of the transmission of the virus of poliomyelitis. Laboratory-bred flies have been permitted to feed on the fresh spinal cord removed from monkeys inoculated with the virus of poliomyelitis and recently paralysed. After feeding, the flies are removed to a fresh receptacle from which certain numbers are removed at intervals, killed with ether, then comminuted with sand and extracted with saline solution, from which a bacteria-free filtrate was obtained by means of a Berkefeld filter. Two monkeys were injected intra-cerebrally with 3 ccm. of this filtrate; the first monkey with a filtrate prepared from seven flies which had lived on clean surroundings for twenty-four hours after having fed on spinal cord, and the second from ten flies forty-eight hours in clean surroundings. Both monkeys developed lesions which at autopsy were found to be typical of experimental poliomyelitis. The authors make this conservative statement. "The experiments recorded merely show that flies contaminated with the virus of poliomyelitis harbor the virus in a living and infectious state for at least forty-eight hours. They do not show that this is the limit of the period of survival and they throw no light on the question whether the virus is retained merely as a superficial contamination or whether it can survive in the gastro-intestinal tract." [E. H. R.]

1. Jopson, after a brief review of the physiology of external respiration and a consideration of various apparatus used in thoracic surgery, discusses the treatment of wounds of the pleura and lung. Conservative measures may result in hemothorax, pressure pneumothorax, emphysema and empyema. The articles of Garré, Stuckey, v. Moeller, Wolf and Grassman are then analyzed. Jopson concludes that the leading indications for operation in penetrating wounds of the chest are: (1) A wound whose situation and direction renders likely penetration of the heart, pericardium or diaphragm; (2) severe primary or recurring hemorrhage, as shown by hemothorax, external bleeding or severe hemoptysis with threatened aspiration of blood into other lung; (3) secondary hemorrhage; (4) severe pneumothorax, especially with symptoms of mediastinal or cardiac displacement, dyspnea, cyanosis and suffocation not relieved by aspiration; also with extensive and increasing external emphysema; (5) secondary pneumothorax (suppuration or sloughing of lung tissue, v. Moeller); (6) empyema. Jopson gives epitomes of eight cases of chest wounds personally observed. He is convinced that too optimistic views in regard to chest wounds and an over-conservative attitude in their treatment will sooner or later lead us all into trouble.

2. Coley concludes his argument that injury is a causative factor in cancer. The medico-legal aspect of the question is first considered and three personal experiences given. Segond's five guarantees necessary to establish connection between injury and tumor are: (1) Authenticity of the trauma; (2) sufficient importance or severity of the trauma; (3) integrity of part prior to injury; (4) correspondence of tumor to exact site of injury; and (5) date of appearance of tumor not too remote from time of injury to be reasonably associated with it. Two more guarantees may be added, vis., the continuous presence of pathologic manifestations, such as pain, at site of injury up to time of appearance of tumor, and histologic verification of the cancer. The opinions of Thiem, Roepke, Ziegler, Gross, Carl, Lowenthal, Lieke, Wolf, Wild, Kirchner and Loewenstein are given. Coley then presents epitomes of 36 cases of carcinoma of the breast associated with antecedent injury and 49 cases of sarcoma of various tissues. He concludes from over 1,200 personal observations that, (1) local trauma of any kind, from chronic irritation to a single local contusion, is not infrequently the direct exciting cause of malignant tumors of all types; (2) a single local injury may cause a carcinoma as well as a sarcoma; and (3) legal liability cannot be admitted until principles and conditions very similar to, if not quite so exacting as, those of Segond are definitely established.

3. Hawkes believes that in a great many cases of typhoid ulcer peritonitis an early diagnosis can and should be made and that better methods should be adopted in order to give the patient the full benefit of such an earlier diagnosis. He lays great stress on the recognition of the very lightest shades of muscular rigidity which accompany the earliest stages of peritonitis. Abdominal tenderness is a less reliable sign; pain is regarded as a sequel of peritonitis rather than a precursor; dullness in the right flank is a valuable sign if present at an early period; rising blood pressure and leucocytosis may both be absent in the earliest stages. The differential diagnosis is considered (appendicitis, intra-intestinal hemorrhage, acute cholecystitis, right lower lobe pneumonia, right-sided pleurisy, extensive splenic infarction or inflammation, kidney

infarction, perinephritis, contusion and hemorrhage into abdominal muscles, distended bladder, costal periostitis, renal or ureteral colic, and suppurating mesenteric glands. Hawkes suggests a hospital with a skilled resident (salaried?) physician with previous ample experience in a large general hospital; a skilled resident (salaried?) surgeon of equal surgical experience; a "special night typhoid service" consisting of rounds made to all waking typhoids every two hours. Resident physician to be notified. In case of muscular rigidity or tenderness he can immediately summon the resident surgeon, who may be operating one or two hours from time of perforation. "Consent o operation should be obtained and recorded on admission in every case where symptoms are present suggestive of typhoid fever." In outside practice among the well-to-do the writer suggests that the practitioner secure the bedside attention of two recent hospital graduates, one for day and one for night duties from the beginning of the third week of the disease. The writer suggests that nurses during their training should be taught to detect the early stages of abdominal rigidity. In this way poorer patients, especially in country districts, would be more frequently saved. Hawkes believes that the presence of a light degree of muscular rigidity and tenderness in the right iliac fossa or right para-umbilical region justify operation. Histories of eleven cases personally operated are given. Hawkes believes that "an early exploratory operation exerts a distinctly beneficial influence, not only on the ulcers that may be about to break down, but on others as well, thus preventing their further progress toward separate perforations."

9. Stewart's experience with Moorhof bone wax differs from that of Simmons (*Annals of Surgery*, January, 1911). He uses it in defects left by removal of fragments in some compound fractures; in acute osteomyelitis as a temporary filling to avoid gauze packing and as a permanent stopper of the evacuated cavity; in all forms of subacute and chronic osteomyelitis, including bone abscess; in tuberculosis of both bones and joints; and in cavities made in healthy bone. He gets first intention in most cases of chronic and subacuate osteomyelitis and tubercular cases. He has never had the wax extruded. On the contrary, granulations have formed over wax which has been exposed by opening of the wound from cutting out of stitches or tension. Five cases are presented with x-rays of four. The period of absorption varies from six weeks to over a year. [T. W. H.]

5. Rosenthal has taken up the fact first mentioned by Cohnheim in 1863, that a diastatic ferment exists in the urine and endeavored to see if it is of value from a diagnostic point of view. He gives a short review of the literature on the subject. He concludes from his studies that although the amount of diastatic ferment may vary in the urine from time to time, the twenty-four-hour urine shows a fairly constant amount of this ferment, which is about 500%. In cases of diminished permeability of the kidney, as in diabetes insipidus and chronic interstitial nephritis, the excretion of this ferment is usually diminished. When the kidney shows increased permeability the ferment comes through and will often come through in cases which, under normal conditions, show no ferment in the urine. In diabetes mellitus the diastatic is nearly if not entirely wanting. [C. F., JR.]

1. The author reviews the literature, which he notes is extremely scanty, of the pathology and surgery of the diaphragm, and reports three cases of his own. Two of these cases were tubercular abscesses of the diaphragm, both were operated on, with resection of a part of the diaphragm. Both recovered.

The third case, a fibrosarcoma of the diaphragm, lived for about six months, following an extensive resection of the diaphragm, and removal of the tumor.

2. The author, by an extremely careful review of the literature, shows that there is considerable doubt in the minds of many pathologists as to the possibility of a tubercular infection of the thyroid occurring.

He details a number of experimental injections into the thyroids of dogs, of both the bovine and the human tubercle bacillus, and reports positive findings at autopsy in a number of the cases. To show that the thyroid is not as susceptible to tubercular infection as other organs, he also injected the bacilli into the spleen, kidneys and testicles of other dogs, and showed that infection is more liable to occur in these other organs. He suggests that the lessened susceptibility of the thyroid to tubercular infection probably has to do, in some way, with its specific function.

7. Looking up this subject in the literature, the author divides the question into four groups, (*a*) lesions of the central nervous system, (*b*) lesions of the vagus nerve, (*c*) lesions of the sympathetic nerve, (*d*) simultaneous lesions of the vagus and sympathetic nerves. He found a surprising difference of opinion expressed as to the amount of damage caused to the stomach by injury to these various nerves, and accordingly instituted a series of experiments. He used both dogs and rabbits. Their stomach contents were examined before and after operation, and the animals were autopsied at varying intervals following the experiments.

The experiments and their results are tabulated as follows.

1. Injury to the vagus.

(*A*) Subdiaphragmatic double vagotomy.

The dogs showed no lesions in the stomach at any time following the operation. The rabbits showed occasional small changes.

(*B*) Subdiaphragmatic single vagotomy.

Dogs negative. Rabbits, one minute change.

(*C*) Both vagi tied off with silk ligatures.

Dogs no results. Rabbits few small changes.

2. Extirpation of the celiac plexus including the celiac ganglion.

Dogs no results. Rabbits, some marked changes.

3. Subdiagphragmatic double vagotomy, with simultaneous extirpation of the celiac plexus including the celiac ganglion.

No changes in either dogs or rabbits.

The stomachs were examined histologically and nothing found, and the author is forced to conclude that the question is not definitely settled as yet. He suggests that another series of experiments be undertaken using another kind of animal.

He found the HCl sometimes increased and sometimes decreased following the operation, in both kinds of animals used. [J. B. S., JR.]

10. KÖLLNER. *The Diagnostic Significance of Acquired Disturbances of Color Vision.*

2. The author reports a number of heart cases treated with ouabain, an infusion decoction of acocanthera. The drug was given by mouth and subcutaneously. He claims that used internally it produces results equal to the other heart tonics and has the added advantage that it may be given subcutaneously without causing the intense pain and the skin reaction, which follows the subcutaneous use of digalen and strophanthine. At present the drug is extremely expensive. He remarks particularly on its marked diuretic action.

5. The figures of this interesting research in Denmark showed that of 2,061 weak-minded patients, only 31, or 1.5%, gave a positive Wassermann, and only 13 of this 31 showed any other taint of congenital syphilis. They conclude, therefore, that congenital syphilis plays only a small part in the production of idiocy among the Danes. Of the epileptics, only one out of 259 cases gave a positive Wassermann.

There were no positive reactions among the blind.

Of the 344 deaf and dumb examined, there were 3 positive reactions. None of these showed any other evidence of congenital syphilis.

The authors conclude, therefore, that syphilis plays no part in the production of the last three affections. [J. B. S., JR.]

6. HOFMOKL, E. *The Law for Protection against Communicable Diseases.*

1. From an extensive microscopic pathologic study of abnormal pigmentation, the author concludes:

(*a*) That the epidermic and connective tissue cells can form pigment of themselves and independently of each other.

(*b*) That the branched pigmented cells of the epidermis are of pure epithelial origin.

(*c*) That the relation between pigmentation of the epidermis and of the cutis is variable.

(*d*) That excessive pigment in the epithelium is extruded from that of the skin, and then taken up by leucocytes and connective tissue.

(*e*) That further pigment distribution may take place by the lymphatics.

(*f*) That the chromatophores in the skin play no part in epidermal pigmentation. [R. M. G.]

## Obituary.

### EDWARD SHIPPEN, M.D., U. S. N.

Dr. Edward Shippen, who died on June 16, at his country home, in Chestnut Hill, a suburb of Philadelphia, was born in New Jersey on June

18, 1826. He received the degree of A.B. from Princeton in 1845, and that of M.D. from the University of Pennsylvania in 1848. He immediately entered the United States Navy, and in April, 1849, was appointed an assistant surgeon. On April 26, 1861, he was appointed commanding surgeon, and in that capacity he served throughout the Civil War. He was on board the frigate *Congress* when it was destroyed by the *Merrimac*; on the *New Ironsides* at both battles of Fort Fisher; and in the squadron that defended Grant's right flank at Bermuda Hundred. After the war he saw considerable service in China and on the coasts of Africa and South America. He was for some time chief medical officer at the Naval Academy at Annapolis. He was on European station as fleet surgeon for four years, and for seven years was in charge of the United States Naval Hospital at Philadelphia. He was promoted to be medical director on March 17, 1876; he was retired in 1888; and in 1907 was given the rank of rear admiral. He was a companion of the Military Order of the Loyal Legion of the United States, and a fellow of the College of Physicians of Philadelphia. He was a frequent contributor to current magazines, and was well-known as the author of several popular books on naval topics.

## Miscellany.

### THE MASSACHUSETTS MEDICAL SOCIETY

#### ANNUAL MEETING OF THE COUNCIL.

THE annual meeting of the Council of The Massachusetts Medical Society was held in the Harvard Medical School, Boston, on June 13, 1911, at twelve o'clock noon, the president, Dr. George B. Shattuck, in the chair, and ninety-three Councillors present.

The treasurer, Dr. Buckingham, read his annual report, showing receipts, including the balance remaining in the treasury from last year, of $31,526.58, and expenditures amounting to $16-781.27, leaving a balance of $14,745.31.

The Committee on Membership and Finance reported through Dr. Goss, recommending that $4,500 of the balance in the treasury of the Society be distributed among the district societies and that nine members be placed on the retired list, the dues of seven remitted, and fifteen allowed to resign.

In accordance with the request of the president that the committee consider the question of the amount to be paid to our representative in the National Legislative Council and our delegate to the meeting of the Council on Medical Education of the American Medical Association for their expenses in attending the meetings of those bodies for the purpose of making recommendation to the Council, and having that body definitely fix the sum to be paid, the committee recommended that the remuneration of these representatives be on the same basis as that of the representatives of the Society in the House of Delegates of the American Medical Association.

Voted to accept the report and adopt its recommendations.

The report of the Committee on Medical Education was read by Dr. Ernst. Dr. Ernst gave notice that the committee will bring up the subject of medical education at length at the meeting of the council next October, as the time was too limited for a full discussion of the subject at the annual meeting. It was voted to accept the report.

Dr. Withington for the Committee on State and National Legislation presented a report of that committee, outlining the activities of the committee during the year. It was voted to accept the report and place it on file.

The Committee on the Assignment of Fellows to District Societies appointed at the last meeting made their report, through Dr. A. T. Cabot, as follows:

REPORT OF THE COMMITTEE.
APPOINTED BY VOTE OF THE COUNCIL, FEB. 1, 1911, TO CONSIDER THE ASSIGNMENT OF FELLOWS TO DISTRICT SOCIETIES.

IN 1875 the Suffolk District Medical Society requested that the Councillors should make "such a definition of the term 'reside,' as it occurs in Article xii of the By-Laws and Digest xii of the Acts, as shall in their judgment be just and equitable to all District Societies."

The Standing Committee on By-Laws of District Societies reported "that the term alluded to a 'legal' and not a professional residence; but it was recommended that, in view of a custom with respect to membership which had hitherto passed without challenge and without real detriment to any Society's interests, the most liberal interpretation be put upon the word in question and that Fellows whose position would be affected by a technical definition of the word be permitted to continue their relations with the District Society of which they have hitherto been counted members."

After discussion, this question of the exact definition of the word "reside" was recommitted to this Committee, who in 1876 reported that they were "unanimously agreed that the word 'reside' is invariably used in the sense of *legal* residence. They therefore recommend that this construction be put upon the word.

Since 1876 that ruling has been in force.

Soon after this a great change began in medical practice.

The specialization, which has constantly increased, has made it less necessary for many practising physicians to live in the midst of their patients.

Many Fellows, wishing their families to have the advantages of country life, have moved out of town while keeping their medical practice in town.

A considerable number of these cases, although coming under the rule, have been overlooked until quite recently, when an exact and proper application of the ruling of 1876 has had the effect of separating many Fellows from the districts in which they have always worked and in which they have acquired influence and usefulness.

Your Committee feel that this change in the habits of medical men has been so great that it is proper to reconsider the action taken by the Council in 1876.

In dividing the State into districts and in assigning Fellows to these districts the prime object was, and must be, to bring together into small units those Fellows who are best able to work together and to help each other towards the objects in which all are interested.

We are associated together for medical purposes, to labor for the health of the community and the improvement of ourselves and our Fellows.

In order that our organization may permit us to attain the fullest success in our efforts for medical progress, we feel that each Fellow should be assigned to the district where his medical activities are. He should be associated with the medical men with whom he is in the habit of working.

Only in this way can his full value of the profession and to the community be utilized. Only in this way can he get in fullest degree the benefits which he has the right to expect from association with his Fellows.

Of the men who have their residence in one district and their professional work in another, a considerable part have changed their residence late in life.

At a time when by education and experience they have attained their fullest value, they are by the present rules uprooted and torn away from the associations of their active life, and their power for good in the profession and the community is greatly curtailed and interfered with.

It seems to your Committee that this is an unnecessary loss of effectiveness.

It seems to us, further, that owing to the conditions of medical practice, aided by the telephone and motor car, the tendency of men to reside away from their place of practice will constantly increase, and that the present rule will work a hardship on an increasing number of Fellows and will curtail the usefulness of the Society in a corresponding and steadily growing degree.

Your Committee have also considered the effect that a more liberal plan of assignments to districts would have upon the District Societies, financially and otherwise. They feel that generally throughout the State the effect would be very nearly balanced, and work no hardship upon any district. In the vicinity of Boston the effect would be more felt and the Suffolk District Society would gain a considerable number of members at the expense of the outlying districts. We feel, however, that the liberal policy that the Suffolk District pursues in the matter of meetings — holding many meetings through the winter in conjunction with the Medical Library (to which the members of outlying districts are invited and where they are always welcome) — offsets this advantage and gives to the other districts greater benefits than they would be deprived of by any readjustment of membership.

Your Committee recommend, then, that the Constitution and By-Laws be amended as follows:

Sec. 5, Chap. 123, of Statutes of 1802, by inserting the words "or practising" after the word "residing" in the fifth line.

By-Law 9 (page 11, line 11), insert the words "or practising" after the word "residing."

Add to this By-Law the following: "Any Fellow wishing to change his membership from one District Society to another may petition the Council in writing to grant such change, stating his reasons therefor. Such petitions shall be referred to the Committee on Membership and Finance, who shall consider the petitions, shall consult with the officers of the two Districts involved in the change, and shall report recommendations to the Council. The Council shall decide by vote whether or not such petitions shall be granted."

Your Committee further recommend that the Committee on State and National Legislation present a petition to the General Court asking for the above change in the Constitution.

Respectfully submitted,

Arthur T. Cabot,
F. Robertson Sims.
Walter L. Burrage.

And it was moved and seconded that the report be accepted and its recommendations adopted.

On motion of Dr. E. B. Harvey the motion was amended as follows:

"Moved, that the report be accepted and the recommendations of the committee as far as the amendment of the By-Law is concerned be adopted. The motion was seconded by Dr. Gay and Dr. Gifford. Dr. A. T. Cabot said that the counsel of the society, Mr. A. D. Hill, had thought that it was wise to amend the charter, but if the entire society was unanimous that there is no need of so doing he was willing to accept Dr. Harvey's amendment. The president put the amended motion and it was adopted by a unanimous vote.

The report of the Librarian was read and accepted.

The Nominating Committee reported the following list of officers:

President, George B. Shattuck, Boston; Vice-President, Ernest S. Jack, Melrose; Secretary, Walter L. Burrage, Boston; Treasurer, Edward M. Buckingham, Boston; Librarian, Edwin H. Brigham, Brookline; and they were elected by ballot.

Dr. Walter E. Fernald, of Waverly, was chosen Orator for the annual meeting in 1912.

The following Standing Committees were appointed:

Of arrangements: G. H. Francis, A. N. Broughton, John Homans, Beth Vincent, W. W. Howell, J. D. Barney.

On Publications: O. F. Wadsworth, Geo. B. Shattuck, E. W. Taylor.

On Membership and Finance: F. W. Goss, Walter Ela, C. M. Green, A. Coolidge, Jr., Samuel Crowell.

To Procure Scientific Papers: T. J. Robinson, F. P. Denny.

On Ethics and Discipline: J. A. Gage, J. W. Bartol, Henry Jackson, G. deN. Hough, S. B. Woodward.

On Medical Diplomas: O. F. Rogers, H. W. Newhall, J. F. Burnham.

On Medical Education: H. C. Ernest, H. D. Arnold, C. H. Williams.

On State and National Legislation: G. E. Shattuck, C. F. Withington, F. G. Wheatley, W. P. Bowers, E. Flagg.

*Incidental business.* To fill the vacancy in the Board of Censors of the Bristol North District, it was voted that E. Washburn, of Taunton, be appointed; in Berkshire District, J. B. Thomes, of Pittsfield and in Hampden District, G. H. Janes, of Westfield.

To fill a vacancy in the Councillors of the Barnstable District, E. E. Hawes, of Barstable, was appointed.

To fill vacancies in the Delegates of the Massachusetts Medical Society to the American Medical Association, I. S. F. Dodd, of Pittsfield, was appointed in the place of Homer Gage and F. T. Murphy, of Boston, in place of O. J. Brown; Alternate Delegates, S. A. Mahoney, of Holyoke

in place of W. A. Dolan and R. I. Lee, of Boston in place of F. W. Anthony.

ANNUAL MEETING OF THE SOCIETY.

At the exercises of the first day of the annual meeting of the society held in the building of the Harvard Medical School, there was an attendance of about 400 fellows on Tuesday, June 13. The experiment was tried this year for the first time of having both morning and afternoon sessions of the medical and surgical sections. These were well attended as were the exhibits in the School. Officers of the sections for the ensuing year were elected by the sections as follows: Section of Surgery, Chairman, William N. Swift, New Bedford; Secretary, R. B. Osgood, Boston. Section of Medicine, Chairman, James M. Jackson, Boston; Secretary, David N. Blakely, Brookline. Section of Tuberculosis, Chairman, A. T. Cabot, Boston; Secretary, John B. Hawes, 2nd, Boston. Late in the afternoon, some 200 fellows attended the demonstrations and exhibits in the Tufts College Medical School, in spite of the inclement weather. The Shattuck Lecture was delivered in John Ware Hall of the Boston Medical Library at 8 P.M., by Dr. Richard C. Cabot of Boston, Subject: Observations Regarding the Relative Frequency of the Different Diseases Prevalent in Boston and Vicinity.

At the one hundred and thirtieth annual meeting of the society in the Harvard Medical School on Wednesday morning, June 14, under the presidency of Dr. George B. Shattuck, the secretary announced that 145 new members had been admitted during the past year, that one fellow had been restored to the privileges of fellowship, 55 deprived of these privileges, 30 had resigned and 42 died, leaving the membership on June 14, 1911, 3,361 fellows.

In response to a communication from the Trustees of the American Medical Association the following resolution was passed: Whereas, The Board of Trustees of the American Medical Association has requested an expression of opinion upon the subject of making in future all members of state societies ipso facto members of the American Medical Association, and in order that the board may make a satisfactory report to the House of Delegates of the national organization relating thereto, be it

Resolved: That as at the present time the Massachusetts Medical Society finds it impossible to devise a scheme whereby the desired object may be attained it respectfully reports to the Trustees of the American Medical Association that the proposition, as far as this state society is concerned, is inexpedient.

The findings and recommendations of the Board of Trial convened to try George W. Galvin of Boston on charges of advertising his method of practice, to wit, that he was guilty and that he be expelled from his membership of the Massachusetts Medical Society, were endorsed and approved by a unanimous vote.

Dr. A. T. Cabot offered the following amendment to the By-Laws:

By-Law 9 (page 11, line 11), insert the words "or practising" after the word "residing."

Add to this By-Law the following: "Any Fellow wishing to change his membership from one District Society to another may petition the Council in writing to grant such change, stating his reasons therefor. Such petitions shall be referred to the Committee on Membership and Finance, who shall consider the petitions, shall consult with the officers of the two Districts involved in the change, and shall report recommendations to the Council. The Council shall decide by vote whether or not such petitions shall be granted."

It was voted to submit the proposition to the next annual meeting of the Society for action.

Papers were read according to the program by Dr. G. W. Gay, W. J. Collins and E. H. Bradford, the last, illustrated by lantern slides being discussed by five members. The annual discourse was delivered by Dr. Maurice H. Richardson, of Boston, title, "The Present Position and Value of the Exploratory or Operative Diagnosis," and at 12.40 o'clock the society adjourned to Symphony Hall where dinner was served to about 1,135 persons. Following the dinner a large number of fellows attended the annual base ball games between nines from the different district societies at the Chestnut Hill Golf Club. The perpetual challenge cup was won by the nine from the Norfolk District.

## RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, JUNE 3, 1911

## Original Articles.

# SUPRAPUBIC INTRA-URETHRAL ENUCLEATION OF THE PROSTATE.*

BY J. BENTLEY SQUIER, M.D., NEW YORK.

THREE general classifications may be made of conditions which arise in the prostate gland warranting surgical attack. First, inflammation; second, benign changes producing urinary obstruction; and third, neoplasm.

It is, however, the second group which presents the greatest number of complexities and in which the etiology is most obscure. The benign pathological conditions which produce urinary disturbance have been loosely referred to as prostatic hypertrophy, and considerable diagnostic confusion has arisen on this account. Therefore, in considering patients suffering from urinary obstruction due to prostatic lesion, it should be kept in mind that such obstruction may exist without any so-called hypertrophy of the organ, or that even enormous hypertrophy may be present without any disturbance of the urinary function. The truth of this is readily understood if the pathology of the prostate is studied. For example, take these two specimens (103 and 231). The smaller was removed from a patient who had complete retention, whereas the other patient, from whom the larger was removed, had no difficulty in passing urine. The prostate in his case was removed because of attacks of profuse hemorrhage from the prostatic urethra. The patient was eighty years of age and still retained vigorous sexual power. The bleeding would follow the act of coitus or prolonged sexual excitement, and the blood would literally pour out of the urethra. An indwelling catheter was the only means of checking the hemorrhage. After four such attacks he submitted to operation. In view of the profuse hemorrhage malignancy was suspected, but frozen sections at time of the operation and examination after failed to demonstrate it. The patient, since operation, has enjoyed coitus without recurrence of the hemorrhage. The operation took place a year ago this month.

Degenerative changes in the prostate are twofold — those taking place in the stroma and those in its glandular structure. In the first instance, an increase in the fibrous elements occurs with a disappearance of the glandular, but with no real enlargement of the prostate. In the other, the glandular structure hypertrophies, with consequent enlargement of the gland.

The mechanics of urinary obstruction may be explained as follows: By the conversion of the prostate into fibrous tissue the bladder neck becomes surrounded by a hard, inelastic ring, and the function of the internal sphincter muscle, which is outside of the ring, is interfered with. This is essentially a retention produced by an alteration in the action of the involuntary sphincter.

*Read before the New England Branch of the American Urological Association, Boston, March 7, 1911.

The obstruction which may accompany an increase of the glandular elements of the prostate is more apt to be the result of the enlargement of the gland causing a deviation in the course of the urethra, or by some outgrowth of the glandular tissue occluding the lumen of the prostatic urethra or the internal meatus.

There is also a third manner in which retention may take place, namely, from changes in the innervation of the bladder and prostate. Surgically, the first two are of chief interest and call for the same surgical procedure. That is to say, removal of the obstruction.

By studying sections of various prostates we find all degrees and combinations of glandular and fibrous-increase between the two extremes of types which I have mentioned. The specimens with microphotographs presented show the basic types of each class. The first one, representing the hard fibrous prostate which has been described under the name of bar at the vesical neck, stenosis of the vesical neck, fibrous prostate, etc., clearly demonstrates how complete retention might eventually occur by a fibrous ring of this character encircling and constricting the vesical neck, while acute retention may occur at any time from an edema produced by a comparatively mild inflammation or circulatory disturbance.

The history of the patient from whom this specimen was removed is fairly typical.

CASE 246. Seventy-five years of age. Obstructive urinary symptoms developed in 1903 during an attack of pneumonia, when catheterization was necessary.

Following recovery from this illness frequent urination day and night obtained, and continued until December, 1909. Complete retention then took place and it was necessary to put him upon catheter life. For one year prior to operation, which was performed in December, 1910, he had had no voluntary urination. The prostate consisted of a band of fibrous tissue, about half an inch in width, surrounding the internal meatus and so narrowing its orifice that it was barely possible to pass a No. 16 F. catheter.

Fibrous degeneration in the prostate of this character would seem to be caused by conditions which produce similar changes in other viscera with gout, rheumatism or syphilis as the predisposing factor.

Under this heading might be placed the contracted vesical neck so often associated with tabes, as well as those cases which many observers believe to be the sequelæ of chronic gonorrhea. These are the prostates which have been described as cases of retention occurring without appreciable enlargement of the prostate. They are trying cases, but may be successfully handled surgically, the management of which I shall describe later on.

The diagnosis is frequently difficult to make before operation, as we have no means of definitely ascertaining the degree of contraction of the vesical neck, unless the bladder is opened and the internal meatus digitally palpated.

The etiology of the second, the purely glandular type, is obscure. Many ingenious theories have been presented to account for it but at present

the situation can be summed up by saying that we know no reason why at a certain time in a man's life an adenomatous change in his prostate should take place any more than we know why myomatous changes are more liable to appear in the uterus at a cetrain period of a woman's life.

Whatever the etiological factor may be in the causation of prostatic hypertrophy or prostatic obstruction, the cure will depend upon its absolute removal. Although, theoretically, we know that a small prostatic outgrowth may be the obstructing factor, and removal of it all that is required to restore the impaired function of the bladder, practically we find it necessary to invariably remove the whole organ if we would feel assured of a successful outcome. It is not an uncommon experience to find that where a prostate has been presumably removed *in toto*, a small teat-like process has been left, and after the patient has recovered from the operation to discover no relief from urinary obstruction.

CASE 235 forcibly illustrates this fact. The patient, sixty three years of age, had perineal prostatectomy performed in June, 1906. Before the operation he had 16 oz. residual urine and almost constant desire to urinate. He had been a sufferer for years from diabetes insipidus, and the abnormal amount of urine excreted added greatly to his discomfort. A stormy convalescence followed the operation and later he developed melancholia, probably due to having experienced no relief from the prostatectomy.

After operation, he was largely dependent upon the use of the catheter, as there was still the same amount of residual urine constantly present. He also had the incontinence of overflow. A year later, cystoscopy showed the presence of unremoved prostatic tissue, as the probable cause of the operative failure. Operation was advised, but was refused at that time.

In June, 1910, the patient having now come under my care, he was again cystoscoped and the findings of the previous cystoscopy verified. Springing from the floor of the internal meatus was a distinct prostatic flap. The mechanical action of this flap was thought to be the cause of the urinary obstruction and operation advised. Suprapubic cystotomy was performed on June 12, and conditions found as seen by cystoscopy.

The prostatic tissue comprising this flap was excised.

Following convalescence, the patient has been able to evacuate the bladder to within 2 oz. There has been no incontinence except on one occasion when it occurred during deep sleep.

The amount of prostatic tissue which remained after the primary operation weighed only a few grains, but was enough to defeat the purpose for which the operation had been undertaken.

The time may come when, by more refined methods of diagnosis, we may be able to ascertain beforehand just which lobe or outgrowth produces the obstruction, and by its removal alone bring about a perfect result; but at present we are unable to do so.

For the sake of argument let us admit that it is imperative to completely remove the prostate in every case, no matter what our preconceived ideas are regarding the particular portion causing the obstruction. In my experience it has seemed possible to feel more certain of the completeness of prostatic removal after suprapubic than after perineal operation. The prostatic lobes do not break up into fragments or lobules so easily during suprapubic enucleation, as often occurs when removed from below, and the chance of overlooking an intravesical outgrowth is practically eliminated. This tendency of the prostate to break up into lobules during perineal enucleation is well shown in specimens of Cases 26, 35, 65 and 72. The explanation is that when enucleating a prostate through the perineum, even though the prostate is drawn downward with a tractor, it is constantly being pushed away and the finger easily slips into lines of cleavage between the lobules rather than keeping just beneath the capsule of the prostate. This is obviously more true of intra-urethral perineal prostatectomy than where the enucleation is made through lateral incisions in the capsule. On the other hand, when working from above downward, the prostate is steadied at three points, i. e., the triangular ligament, the pubic arch and by the fingers in the rectum, thus facilitating adherence to the original and correct line of cleavage. The thoroughness of suprapubic removal is exemplified in specimens Nos. 106, 130, 226, 227, 239, 241 and 248.

If further argument be necessary for complete prostatectomy, the ever-present possibility of unrecognized carcinoma may be offered. Many early cases give histories and symptoms in no way differing from benign hypertrophy. Specimen 207, which was removed from a patient eighty-one years of age, illustrates this. He had been on catheter life from some months and only submitted to operation because of increasing difficulty in passing his catheter. At the time of operation the prostate was removed without difficulty and macroscopically did not differ from benign hypertrophy. Nevertheless, when sections were made of the various lobes, carcinomatous changes were found, but only in the anterior commissure.

Another point, and one which I believe will reduce the mortality rate of prostatectomy more than anything else, is lessening the length of time the patient is subjected to anesthesia during operation. In most instances, we are dealing with a class of patients who can little withstand any surgical procedure, and absolutely cannot withstand any operation which necessitates prolonged narcosis. This brings me to the subject which is uppermost in my mind in regard to prostatectomy, namely, why I have chosen the suprapubic prostatectomy as the operation of election in the great majority of my patients.

During my early work in prostatectomy I used the perineal method of removal most frequently. This is shown by the first one hundred cases, in which seventy-one were perineal operations, to twenty-nine performed suprapubically. From this series I learned many things, which made me feel that for me the perineal operation was not ideal. The average end results of the suprapubic

operations were more brilliant than the perineal, post-operative incontinence of urine never occured, and I was led to believe that if the difference in mortality of the suprapubic over the perineal could be removed I would feel inclined to use this method of prostatectomy exclusively unless very definite indications were present for perineal operation.

Death following prostatectomy by either method is usually caused by shock, renal insufficiency or pulmonary embolism, and thinking that the first two of these causes could be somewhat influenced by improvement in the technic of the operation, I have steadily worked with that end in view. Shock following any surgical operation, leaving hemorrhage out of consideration, is in direct proportion to the length of time required to perform it and the amount of anesthetic the patient consumes. The ability of the kidney to properly functionate is also reduced by prolonged anesthesia, therefore, indications exist for a rapid operation as well as to conserve the vitality of the patient in every way before, during and after the operation. The technic which has greatly improved my results I shall take the liberty of giving at length, as the carrying out of the little details is so essential. I am not trying to place before you a new operation for prostatectomy, but to show what I consider to be the points which are of importance in performing suprapubic prostatectomy, and some of the reasons for their importance.

In outlining this technic, we will assume that the patient to be operated upon is suffering from simple enlargement of the prostate without complications. Twenty-four hours previous to the operation the abdomen and pubes are shaved and thoroughly washed with green soap, and a dry sterile dressing applied. At the time of operation, the patient is brought to the operating room, placed upon the table, the bladder irrigated and distended with a sufficient amount of fluid. The operative field is sterilized by the tincture of iodine method. Sterile towels are placed on the patient and he is made ready for operation before anesthesia is commenced. The advantage of this method of preparation is that the patient is not compelled to lie in a pool of water with the opportunity of a chilling of his body surface as by the old method of sterilization, where the final preparation consists in soap and water scrubbing of the patient's abdomen, and application of alcohol and ether and solutions of bichloride of mercury to the parts after the patient is under the anesthetic. Instead, he is kept warm and dry right up to the time when the incision is made.

After all preliminary preparation has been completed and the towels arranged, and the surgeon is ready to commence operating, and not until then, is the anesthesia started. My perference for the anesthetic is ether, given by the drop method. The reason is that it is the safest general anesthetic where complete anesthesia is necessary, and complete anesthesia is necessary, if only for a few moments, in performing this operation rapidly. This is explained as follows: After the abdominal incision is made and the bladder opened, complete relaxation is desirable to make the enucleation of the prostate easy, because if the patient is not fully under the anesthetic the rectus muscles will so tightly grasp the operator's fingers that it will cause them to tire quickly and thus interfere with the rapidity of the enucleation. The enucleation of the prostate having been accomplished, the anesthetic is discontinued, making the interval of time during which the patient has been in complete anesthesia only a few minutes.

The abdominal incision having been made and the bladder exposed, the incision in the bladder, large enough to admit two or three fingers, should be made high up on the fundus close to the peritoneal reflection. (*Plate* 1.)

Plate 1.

This may seem to be an unimportant matter, yet it has a direct bearing on the length of time required for the healing of the suprapubic sinus. A glance at *Plates* 2 and 3 will explain the reason at once. If the opening is made low down behind the pubic bone through fear of injuring the peritoneum or otherwise (*Plate* 2), when the patient's convalescence permits him to assume an upright position, the bladder opening of the suprapubic sinus is in a relatively dependent portion of the bladder, thus facilitating the constant escape of urine through the sinus (*Plate* 3). Such a condition will undoubtedly increase the length of time necessary for healing to take place. This is especially true in patients who have relaxed abdominal walls with large dilated bladders.

The method of enucleation of the prostate which I prefer varies from the description usually given

PLATE 2.

and is of very considerable importance as it materially aids in reducing the length of the time of the operation. The details of the method are: Do not seek the most prominent lobe of the prostate and commerce enucleating by boring through the bladder mucous membrane at this point, but insert the finger into the internal meatus and break through the roof of the prostatic urethra. (*Plate* 4.) Access is at once given to the line of cleavage between the lateral lobes just beneath the anterior commissure. The enucleation is then begun by working the finger upward and forward, freeing the apex of the prostate from its capsule in the region of the triangular ligament. (*Plate* 5.) A sweep of the finger frees it in front and on one side, then in like manner on the other, and the prostate is turned into the bladder, with its apex pointing upward, when a little separation from the capsule posteriorly completes its removal. (*Plate* 6.)

Carried out in this way, with a little care, there is practically no danger of injury to the rectum, and the enucleation is rapid and complete. Sufficient evidence is now on record to show that a removal of a part or all of the prostatic urethra in no way militates against perfect restoration of urinary function. Theoretically, if this method is used, the resulting wound in the bladder is on a higher level than if the bladder mucous membrane had been incised over the most prominent prostatic lobe, and during the subsequent drainage of the bladder is less liable to be constantly bathed in urine. An assistant slips his fingers into the rectum to push up and steady the prostate during removal. The operator should not put his fingers into the rectum. The objections are twofold: First, it interferes with the immediate completion of the operation, as resterilization of the hands and the changing of gloves is at once necessitated; second, because such resterilization consumes valuable time which should be saved the patient.

The prostate having been removed from the bladder, a double drainage tube, whose total caliber is about No. 32 F., is inserted into the bladder wound and sutured at its upper angle by a chromic gut stitch, allowing the drainage tube to project into the bladder three quarters of an inch. To secure efficient drainage, the proper placing of this tube is important, and this stitch through the bladder holding it in position for perfect drainage should not be omitted, even though a second one is placed through the skin to take off any undue strain. The lower angle of the bladder incision is accurately closed up to the tube with chromic gut sutures. The abdominal wall is closed with three or four figure-of-eight silkworm gut sutures, one loop of the stitch approximating the fasical plane and the other loop the skin. As soon as the drainage tube has

been sutured into position, hot saline irrigation of the bladder is commenced and continued during the remainder of the operation through this double tube. By the time the abdominal wound has been sutured all active hemorrhage will be practically checked. A prostatectomy carried out in this manner can be completed in five or six minutes, and the patient need be completely under the anesthetic but two or three. By the time the dressing is applied he is usually well out of the influence of the anesthetic.

Plate 3.

The description of the operation just given applies, as I remarked, to the simple enlargement of the prostate gland without complications; but, on the other hand, it has also been my most efficient means of dealing with small fibrous prostates or fibrous contraction of the vesical neck, and has given results vastly preferable to those obtained by simply incising the vesical neck by glavanocautery or the knife. The ease with which these fibrous prostates can be removed is wholly dependent upon the point where the enucleation of the obstructing tissue is commenced. It is comparatively simple to remove tight fibrous bands of prostatic tissue obstructing the vesical neck if the proper line of cleavage is discovered, and, if the prostatic urethra is opened upon the side or its roof, this line of cleavage is readily found.

Plate 4.

In the treatment of patients suffering from

prostatic obstruction complicated with foul cystitis, advanced kidney disease or otherwise, every means to improve the general and local condition should be used before any operation is undertaken. The simpler procedures, such as

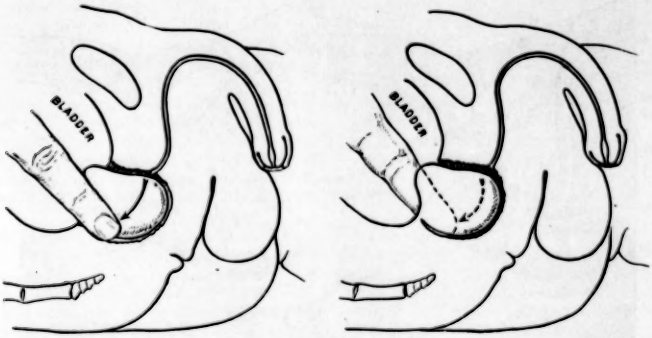

PLATE 5.

frequent bladder irrigations, an indwelling catheter, attention to the details of medication and nursing, have been all that have been required in most instances. In my opinion, the two-step operation for prostatectomy, namely, primary cystotomy for drainage followed later by prostatectomy, has been altogether too much exploited. Some surgeons have gone so far as to advise it as a routine procedure. I have found that if it is necessary to open the bladder for drainage, the few extra moments required to remove the prostate has not jeopardized the patient.

PLATE 6

CASE No. 247 is illustrative.

The patient, a gentleman seventy-six years of age, with advanced degenerative changes in his kidneys, heart and arteries. He was brought into the hospital late last New Year's Eve with a bladder distended above the umbilicus. He had not passed urine for eighteen hours, and for some hours previous to the time when I was called to see him, repeated unsuccessful attempts to pass a catheter had been made. I made a further attempt to catheterize him and also failed, the catheter being obstructed within the prostate. The prostate felt large by rectum. A history of prostatic symptoms extending over a period of years was obtained, but he had never had complete retention before. His condition was alarming, he had a rapid, weak pulse, there was great prostration and fine râles could be heard all over the lungs.

It was decided to open the bladder at once. He was, therefore, conveyed to the operating room, placed upon the table and a coat of iodine painted over the lower abdomen, a few sterile towels arranged and the patient was ready. It was thought best to give him a few whiffs of ether and to open the bladder under primary anesthesia. This was done, the ether acted as a cardiac stimulant, and his condition improved. At the moment of primary anethesia, the bladder was opened. Fifty-odd vesical calculi were found with a large obstructing prostate. The stones were scooped and irrigated out, and the patient's condition having progressively improved since the ether was started, the prostate was removed as well.

A little time was lost in scooping out the calculi, and twelve minutes elapsed from the time the anesthetic was started to the completion of the dressing. The total time during which ether was administered was seven minutes.

The prostate removed showed that a false passage had been made into it. through the prostatic urethra, accounting for the failure in passing a catheter. The false passage can be plainly seen in the specimen. The patient's convalescence was uneventful. At the end of two weeks the wound was tightly closed, which is rather early after suprapubic prostatectomy, and he was voiding urine.

I do not cite this case as remarkable, for it has not been an uncommon experience; nevertheless, if the bladder had been only drained, leaving the prostate for later removal, I might have felt that the primary drainage had made successful prostatectomy possible.

It would seem that the two-step operation has a very limited field and should be kept for such patients suffering from sepsis and running a temperature, and in whom the use of an indwelling catheter is impractical or catheterization

impossible. The preliminary cystotomy for drainage should then be performed under novocaine anesthesia.

The only fatalities following suprapubic prostatectomy I have had during the period of the last two years occurred in two patients who died of pulmonary embolism. This was in a series of sixty-seven operations. Death from this cause is apparently unavoidable, and probably is especially liable to occur after prostatic operation, the direct connection of the prostatic veins through the hemorrhoidal to the right side of the heart being doubtless the predisposing factor. In operations upon viscera whose veins empty into the portal circulation, pulmonary embolism is rarely observed, explained, possibly, by the emboli being arrested and absorbed in the liver.

I would not, however, minimize the risks of prostatectomy. A certain percentage of deaths will come to every operator. Patients will succumb to ether pneumonia when least expected, and with no discoverable fault of the anesthetist. Renal insufficiency will claim its quota, for there is no absolutely accurate means of determining before prostatectomy the postoperative functional capacity of the kidneys. The recent phenosulphophthalein tests, although an advance, cannot be considered as giving the final word upon the advisability of operation. We still have to be guided by the examination of the twenty-four-hour excretion, and this has been notably inadequate in the past.

I am convinced that the percentage of death following prostatectomy by either suprapubic or perineal methods will differ but little when performed by equally competent surgeons.

One thought in conclusion: Many have discredited prostatectomy because they have been led to expect the impossible from it. Therefore, the patient should be warned that, by removing the obstruction to urination, it does not necessarily follow that perfect compensation can be restored to a bladder which is already a mass of degenerated muscle fiber, connective tissue and diverticulæ; and the surgeon should realize that the removal of the prostate is often the simplest part in the management of a chronic infection of the genito-urinary tract. It may be but the first step towards a cure which will require weeks or months to consummate.

## THE VALUE OF THE GUINEA PIG TEST IN GENITO-URINARY TUBERCULOSIS.

BY J. DELLINGER BARNEY, M.D., BOSTON,

*Assistant Surgeon to the Genito-Urinary Out-Patient Department, Massachusetts General Hospital;*

AND

EDWARD L. YOUNG, JR., M.D., BOSTON,

*Graduate Assistant, Genito-Urinary Out-Patient Department, Massachusetts General Hospital.*

In an article entitled "Specimens of Tuberculosis of the Kidney in which guinea pig test was negative,"[1] Tenney, of Boston, reports three cases of nephrectomy "for pain, with pus and blood in the urine, and frequent and painful micturition. The symptoms of disease had been present in these patients for four, six and three years. In every case the urinary sediments had been injected into guinea pigs, — twice with one patient, — and the autopsy findings on the pigs after six weeks were negative."

"Two of the removed kidneys were examined at the Harvard Pathological Laboratory and the other at Tufts. The diagnosis returned to me was tuberculosis in each case."

Tenney concludes his paper as follows:

"There is, then, no constant stream of bacilli flowing out of a tubercular kidney, and while the presence of tubercle bacilli in the properly obtained sediment proves their source to be in the urinary tract, their absence proves nothing so far as diagnosis goes."

These cases having brought to our attention the possibility of error in the "guinea pig test," we have examined the records of the inoculations done in the Clinico-Pathological Laboratory at the Massachusetts General Hospital with reference to determining the percentage of error occurring in a large series of cases.

The technic is the following: The urine is drawn from the bladder by a catheter, or from one or both kidneys by ureter catheters in the course of a cystoscopy. The specimen is then centrifugalized, except in the event of its being distinctly foul, or of there being an uncommonly heavy sediment. Under these circumstances it is simply allowed to stand for a few hours and the sediment is then taken. From twenty to forty minims of this urine is then injected under the skin of the pig's abdomen (occasionally direct intraperitoneal injection has been accidentally done). One pig is inoculated with each sediment, and is killed at the end of five weeks. Immediate autopsy is performed. Smears from the diseased organs and lymph nodes are stained, and the presence of the tubercle bacillus demonstrated by the microscope. The diagnosis is thus proved microscopically and macroscopically.

In most cases a culture of the urine is made at the same time. When positive, these cultures have shown the usual bacteria of urinary infection, notably bacilli of the colon group and the staphylococcus albus. That the very frequent presence of these bacteria rarely injures the guinea pig is shown by the fact that, in the large number of inoculations collected, death from sepsis has been a rarity. That the value of the test for tuberculosis is in no way impaired is shown by the figures which follow.

These figures are based on the unselected records of guinea pig inoculations for suspected tuberculosis during the two years from January, 1909, to, and including, January, 1911. In this period of time a total of 252 consecutive inoculations have been done. These have been divided into two large groups: First, where the test was positive; second, where negative results have been obtained. In order to make the results of this investigation as indubitably accurate as possible, each group has been subdivided into those cases in which unquestionable proof of the

[1] Boston Med. and Surg. Jour., Feb. 16, 1911.

accuracy of the test is at hand in the form of operation with a pathological report of the organs removed, autopsy, long-continued clinical observation, or repeated inoculations. The second subdivision includes those cases where only clinical evidence, with or without cystoscopy, and of usually brief duration has been obtained.

The results may be briefly tabulated as follows:

| | |
|---|---|
| 1. Total number of guinea pigs inoculated, | 252 |
| 2. Test positive in | 67 |
| (*a*) Proved, | 58 |
| (*b*) Unproved, | 9 |
| 3. Test negative in | 185 |
| (*a*) Proved, | 139 |
| (*b*) Unproved, | 46 |
| 4. Total number of tests proved, | 197 |
| 5. Test *negative*, pathological report or autopsy *positive* | 2 |
| 6. Percentage of error in guinea pig test, | 1.01 |
| 7. Test positive, no tuberculosis of the urinary tract | 1 |

Certain items of the foregoing table need explanation and elaboration. Firstly, it is fair to say that there can be no reasonable doubt of the accuracy of the guinea pig findings when the results are positive. The animals obtained by and used at the Massachusetts General Hospital are all carefully selected for their health and vigor. They are kept in a specially constructed room under the best of hygienic conditions, and none but vigorous animals are used for the test. It is common knowledge that the guinea pig is peculiarly susceptible to tubercular infection. Hence its value for inoculation purposes. But it is extremely rare, in the experience of our laboratory, to lose an animal from accidental tubercular infection.

The following case illustrates the care which is taken in ruling out this possibility, and it is the only one of its kind in this series.

Guinea pig inoculated April 2, 1909. Forty minims of urine injected under the skin of the abdomen. Killed May 4, 1909.

"Autopsy shows tuberculosis of the maxillary and mediastinal lymph nodes and spleen. No tuberculosis of the axillary or inguinal lymph nodes. Inasmuch as the animal was inoculated subcutaneously in the abdominal wall, this tuberculosis in the animal must be regarded as infection by the mouth and not as the result of inoculation."

A subsequent negative inoculation proved the accuracy of this observation. It, therefore, may be said without reasonable doubt that in the tests comprising this series a positive result needs no further proof. The subdivision of item No. 2 is then unnecessary.

It is seen that the number of negative tests outnumber the positive by about three to one. It must be remembered that in a large modern hospital many tests are made simply to complete a case and because the facilities are at hand. The patient is given the benefit of any doubt as to his disease. Many inoculations have, therefore, been made to exclude tuberculosis, and others only because such a diagnosis seemed remotely possible.

The standard required for proof in these negative cases has already been mentioned, and it has been strictly adhered to. In going over the clinical records of the forty-six "unproved" cases there were many where cystoscopy showed no characteristic tubercular lesions of the bladder, where the urine showed no blood and perhaps only a little pus, or where there were no urinary symptoms whatever. Such cases we personally consider to be non-tubercular without reasonable doubt, yet we do not include them in the "proved" series.

Of special interest is item No. 5 of the above table. In the presence of undoubted tuberculosis, as shown by the surgeon and by the pathologist, the guinea pig did not react in the following cases:

CASE 1. E. S. 592–105.

*Clinical diagnosis.* — Tuberculosis of kidney and bladder.
*Urine* contains no blood or pus.
*Cystoscopic* picture characteristic of tuberculosis.
*Operation.* — Nephrectomy, ureterectomy.
*Guinea pig test* negative (bladder specimen).
*Culture* from kidney shows no growth.
*Pathological report.* — Tuberculosis of kidney and ureter. *Ureter completely obliterated.*

The lessons taught by this case are that (1) no urine may come from the kidney owing to an obstruction of the ureter, and (2) in obtaining a urine for guinea pig inoculation at least a part of it must come from the diseased organ. Hence it is wise to always make certain that urine is coming into the bladder from both kidneys, or to obtain the urine directly from each kidney (or at least from the one under suspicion) by means of the ureter catheter. Had these steps been taken in this case there can be no doubt as to the results of the guinea pig test. Under the circumstances, however, it must serve as an example of the possibilities of error on the part of the guinea pig.

CASE 2. S. S. 117–255.

*Clinical diagnosis.* — Abscess of right kidney (tubercular).
*Urine* contains blood and pus.
*Cystoscopy* not done.
*Operation.* — Nephrectomy.
*Pathological report.* — Tuberculosis.
*Culture* from pus in kidney shows no growth.
*Guinea pig test* negative.

In other words, here is a case similar to those which form the introduction to this paper, the only one of its kind occurring in this series. We shall not attempt to explain it beyond saying that there is nothing infallible in the science of medicine. One statement of fact may be worth while. We said at the outset that our guinea pigs were killed at the end of thirty-five days, a period of time which the experience of the hospital has shown to be sufficient to produce the desired result. The animal in this case was killed at the end of thirty-three days. Surely a difference of two days would not make the difference between a positive and a negative result. It is fair to say that guinea pigs, like all other animals, human and otherwise, have each their

special power of resistance to infecting agents. It is conceivable that the animal in question was of unusually high vitality, or that the tubercle bacilli in the urine were few in number or of low virulence. We are even willing to admit the possibility of a misstep along the path from patient to pig. Whatever the case may be, the record stands. As a matter of fact, a period of five weeks, or even of six weeks (which the Boston Board of Health Laboratory requires), is too short a time for a proper test. Two or even three months is necessary, in the opinion of many authorities, to demonstrate the presence of the tubercle bacillus. For clinical purposes, however, the lapse of five or six weeks is apparently sufficient, in the majority of cases, and, in fact, is all that we can afford to allow in the way of delay to our patients. Had the guinea pigs inoculated with the urines which are reported as negative in our series and in Tenney's cases been allowed to live for two or three months, the results might have been different in some of them. These would have been the cases in which, if the tubercle bacillus was present at all, it occurred in greatly diminished numbers, or was of an unusually low degree of virulence.

Should we exclude Case 1 (which we might fairly do) on the grounds that the guinea pig was not given a fair chance to show his worth, it reduces the percentage of error to the remarkable fraction of 0.5, which in a total of 197 conclusive tests is not at all discouraging.

Item No. 7 in the table is worthy of some detail as showing the possibility of the escape of tubercle bacilli through a non-tuberculous kidney.

Case 3. E. M. 729-13. Female.

*Clinical diagnosis.* — Subacute glomerulonephritis, Vincent's angina, lobar pneumonia, acute fibrinous pericarditis, pulmonary tuberculosis, hematuria.
*Urine* contained blood, casts and renal cells.
*Guinea pig test* positive.
*Autopsy* showed chronic glomerulonephritis, pneumonia, tuberculosis of bronchial lymph nodes, tuberculosis of superior lobes of lungs.

The occurrence of such a case not only confirms our belief in the permeability of the kidney to bacteria, but also opens up a subject which others have touched upon and which we hope to follow to a definite conclusion at some future time. It demonstrates also the extreme delicacy of the guinea pig test, for it is not reasonable to suppose that the number of tubercle bacilli filtering through a non-tuberculous kidney is large at any one time.

Before closing we wish to recite briefly the histories of three cases having all the "earmarks" of tuberculosis, but in which the guinea pig, microscope, operation or long observation showed us our error.

Case 4. W. S. 647-1.

*Cinical diagnosis.* — Tuberculosis of left kidney, tuberculosis of left epididymis.
*Urine* contains blood and pus.
*Culture* of urine shows staphylococcus albus.
*Cystoscopy* showed a typically tubercular bladder, with delayed and scanty secretion of urine from the left kidney.
*Operation.* — Nephrectomy, ureterectomy, epididymectomy.
*Pathological report.* — Kidney, pyelonephritis; Ureter nearly obliterated and containing much fibrous tissue; epididymis, chronic inflammation.
*Guinea pig test* negative on two occasions.

Case 5. E. M. 173025; S. S. 146-115; 156-53. Female.

*Clinical diagnosis.* —Genito-urinary tuberculosis; debility.
June, 1907. Left nephrectomy. *Pathological report* showed tuberculosis. Considerable ureter left behind. *Cystoscopy* showed tuberculosis of the bladder; no ureter catheterization. Condition of right kidney undetermined, but evidently good, as patient stood operation well. No guinea pig inoculated, but urine contained blood and pus.
December, 1907. Second operation for curetting sinus of loin from ureteral stump.
January, 1909. Patient came to the Accident Room in response to a letter. General improvement and gain in weight. Slight urinary symptoms persist. Occasional mild pain in right costovertebral angle.
November, 1910. Patient works every day, keeps her weight and strength. Diuria every two or three hours; nocturia once or twice. Pain in right side, with some tenderness. Urine contains blood, pus and mucus.
*Cystoscopic* picture resembled tuberculosis in many ways, but considered to be "acute colon infection." Right ureter not catheterized.
*Culture* of urine shows staphylococcus albus.
*X-ray* not taken.
*Guinea pig test* negative.
Forced feeding, rest in bed, and sandalwood oil wrought much improvement. Right kidney palpable, slightly tender. Urine showed only pus, no blood or mucus. A subsequent report from the patient's physician shows her to be in good condition and working every day. No further details could be obtained.

Case 6. W. S. 561-231.

*Clinical diagnosis.* — Tuberculosis of the bladder.
*History* characteristic.
*Urine* contains blood and pus.
*Culture* of urine negative, but later staphylococcus albus was found.
*Guinea pig test* was negative.
*Cystoscopy* thought to show tuberculosis. A second examination showed a tumor of the bladder.
*Operation* revealed an inoperable tumor of the base of the bladder.

These cases are to be considered simply as further evidence of the extreme reliability of the guinea pig in the final decision.

Let it not be understood from what we have said that absolute immunity from error in the diagnosis of genito-urinary tuberculosis is claimed for either the surgeon, the pathologist or the bacteriologist at the Massachusetts General Hospital. It has been shown that all are at times in the wrong. What we have attempted to prove is that the guinea pig test for tuberculosis, when carefully done, is by far the most delicate and invariably accurate diagnostic weapon at our disposal and that a negative test is of indisputable value.

## REMARKS ON A FORBIDDING CASE OF CANCER INVOLVINC TONGUE, TONSIL AND PHARYNX PERMANENTLY CURED BY RADICAL EXCISION.

BY MAURICE H. RICHARDSON, M.D.

SOME years ago I reported a case of total excision of the pharynx for cancer, with a permanent esophagostomy.[1] Herewith I report a case of partial excision of tongue, tonsil and pharynx for cancer, with no recurrence at the end of five years. It may be not inappropriate for me to give the reason for publishing these cases. It is not that operations in hopeless cancer may be multiplied, — far from it, for there are too many now, — but rather that we may encourage operation in apparently hopeless cases which are not so bad as they seem; that we may discriminate more accurately between the cases really inoperable and those only apparently so; that we may thus save from the horrors of hopeless cancer a few discouraged and discouraging patients.

The only way we can improve our treatment is by improving our prognosis. The case must, therefore, be considered before operation from the point of view of prognosis.

Upon what does the prognosis depend, as gauged before operation is attempted or even advised? Upon an accurate diagnosis, of course; upon the extent of the disease; upon its virulence; upon the patient's powers of resistance; upon the thoroughness of operation. To give every one of these elements its proper weight, the surgeon must have had a large experience and must have marked common sense.

From a vast number of cases of cancer — operated upon and unoperated upon — I select one which, from its situation and extent, seems in its operative prognosis one of the most hopeless.

I like to bring forward cases like this to show that we may be too much inclined to pessimism. I admit that the results as a whole are only too discouraging, and it is, therefore, no wonder that we are pessimistic. It is no wonder, too, that we are pessimistic, because, in spite of a success here and there, the results show the real hopelessness of our prognosis. We may have so many complete failures in the course of years that we shall forget the possibility even of success. I admit such gloomy prognostications in many cases that it seems hardly worth while to inquire the outcome at all, and then only to learn the time of recurrence and the date of death. But things are not always as bad as they seem. This case, in fact, helps us to tell why some cases are not so bad as they seem; it helps us to decide when under seemingly hopeless conditions that hopelessness is apparent rather than real; it tells us why the contra-indications to operation that have so long prevailed may not be based upon sound reasoning or accurate observation; it tends to prove that, for some reason perhaps not yet fully understood, certain attributes of a case differ in prognostic value, though it may not tell just why; it helps in a small way to solve the problem of operative surgery in advanced cancer; it shows that there is a difference in virulence of the growth, or in the meaning of infiltration as we ordinarily understand the word.

Mr. J. E. F., aged sixty-one, hotel-keeper, was a patient of Dr. F. E. Sweetsir, of Merrimac, Mass., who sent him first to Dr. J. W. Farlow. On Dec. 10, 1905, Dr. Farlow referred him to me with the diagnosis of malignant disease of the right tonsil and pillars of the fauces. He had found nothing abnormal in the larynx. There was a good family and personal history, but the patient was a great user of tobacco. A year before this he had had a soreness of the tonsil which disappeared on his giving up smoking. In September, two months and half before my examination, the patient noticed soreness and swelling in the right tonsil, like that of a year before, but it did not disappear. There was little pain or difficulty in swallowing, and nutrition had been in no way impaired. The heart, lungs and kidneys were normal, but there was a marked arteriosclerosis. There was also a chain of enlarged and presumably infected lymph nodes from the angle of the jaw to the sterno-clavicular joint.

I considered the prognosis carefully in this case and finally consented to make an attempt at radical cure, in spite of the situation of the disease and the diagnosis, both of which were discouraging in the extreme. In coming to this conclusion I was influenced favorably by the case of Mrs. J., referred to me also by Dr. Farlow, in whose case complete recovery followed total extirpation of the pharynx with permanent esophagostomy.[2]

The operation on Mr. F. was performed Dec. 12, 1905, at the Corey Hill Hospital. The ether was given by Dr. Garland. A curved incision, with its convexity downward, was made from the mastoid process to the symphysis of the jaw. A second incision was made from the middle of this downward nearly to the sternum. The submaxillary and the carotid triangles were then thoroughly dissected. The posterior belly of the digastric muscle was cut at the anterior end, and the muscles at the base of the tongue on the right side were divided. A mass of cancerous glands about an inch and a half in diameter were found deep in the carotid and subclavian triangles. After I had tied the carotid artery just above the superior thyroid branch, a mass of new growth involving the tonsil, the tongue, the pillars of the fauces and the pharynx was separated by a fair margin of contiguous healthy tissue. This mass, with a chain of glands running down in front of and to the outside of the carotid sheath, was dissected away nearly to the sternum. After this mass had been isolated on all sides by free dissection, an opening was made into the back of the mouth, just in front of the tonsil. A strip along the side of the base of the tongue was next dissected down to the tonsil. The tonsil itself was cut away with a good margin of normal-looking mucous membrane. The gap left in the tongue and in the pharynx by the removal of this mass was partly closed with chromic catgut. The wound in the pharynx was then packed with gauze. This patient made a good recovery and was discharged from the hospital Jan. 11, 1906.

I supposed that long ago there had been recurrence and death, but on Feb. 1, 1910, the patient was reported by a friend to be in good health. On Feb. 3, 1910, Dr. Sweetsir wrote me that he had seen Mr. F. within a month; that he was well and strong and weighed about two hundred pounds; that his hotel had been destroyed and he had just erected a new one.

In March, 1910, Mrs. F. wrote me that her husband

[1] See BOSTON MED. AND SURG. JOUR., Nov. 5, 1908.

[2] BOSTON MED. AND SURG. JOUR., Nov. 5, 1908.

had not been so well for years. "You would be surprised," she said, "if you knew all the hard work he has done since the first of September."

On Feb. 11, 1911, I made a very careful examination of the throat, and found not the least sign of recurrence.

Dr. Whitney's report was a follows:

HARVARD MEDICAL SCHOOL,
BOSTON, Dec. 18, 1905.

*Dear Dr. Richardson,* — The specimen from Mr. F., Dec. 12 (C. 512 — 2), consisted of portions of the tonsils which were occupied by a superficially infiltrating new growth, opaque, white, with an ulcerated surface.

With this there were also some enlarged lymph nodes and a piece of the submaxillary gland.

The growth from the tonsil consisted of folded masses of large epithelial cells infiltrating the tissue and reaching well down to the muscular layer.

Microscopic examination showed the growth to be made up of flat epithelial cells in large columnar-like masses invading the tissue of the tonsil.

Microscopic examination of the lymph node showed invasion in places with a similar new growth. The submaxillary gland presented nothing abnormal.

In addition, there was also a piece of tissue from the soft palate which showed infiltration with a similar new growth.

Diagnosis: Epithelioma.

Yours very truly,
(Signed) W. F. WHITNEY

I do not know that others are as profoundly discouraged in the treatment of cancer as at times I am; but occasionally it does seem that there is absolutely no use in trying operative surgery. But we must keep up the fight in spite of all discouragement, and, more especially, in spite of the hopes that are held out by new non-operative methods.

We forget, do we not, our successes; we do not even know that we have had them. We do not find because we do not seek. I fully believe that if we look into our remote results, we shall find, in some of the apparently discouraging cases, renewed hope.

Could we succeed by any non-operative method as well as we now succeed with the operative, the instrumental treatment would vanish from the earth. We despond because we see and hear only of our failures; we often do not know of our successes.

It is the object of this and of succeeding papers on malignant disease to call attention to the successes of our excisions and to replace a too deep despondency by a not too exuberant hope. And if we cannot find renewed hope in operative surgery, I have faith that in the near future we shall find a cure in the use of serums, toxins, vaccines or other non-operative methods.

## Clinical Department.

### A CASE OF DIABETES TREATED BY FEEDING OF CALVES' PANCREAS.

BY WILLIAM H. COWLES, M.D., AYER, MASS.

C. P. was twenty-three years old in 1894. His family history was good, there had been no diabetes among near relatives. He was of large frame and good muscular development, with a normal weight of 190 lb. He was active and athletic, always having a place on the football teams of his school and college.

He trained and played during the football season of 1893, feeling very well. In December of that year he lost flesh and strength.

In February, 1894, it was discovered that he had diabetes and he was put on the usual diabetic diet with only moderate improvement.

He first came under my observation in August, 1894, and was then much reduced in weight. Urine, 6–8 quarts in twenty-four hours; specific gravity 1035-38.

He lived an out-door life, taking much exercise during 1894–5–6, following the usual diabetic regimen very faithfully.

He also took a long course of alkaline mineral water and arsenic with some improvement for a time.

Many other remedies were tried with only transient benefit. During the latter part of 1896 he failed steadily, losing flesh and strength. His urine was 7–10 quarts; specific gravity, 1040–1045.

Early in January, 1897, he was extremely emaciated, resembling one in the last stage of pulmonary consumption and unable to leave his bed. His breath had a strong odor of acetone, he was also dull and somnolent for several days. His death was expected at any time.

The relation between pancreatic disease and diabetes was just then under frequent discussion and led me to try pancreatic feeding.

A regular supply of fresh calves' pancreas was procured from a nearby slaughter house. Fortunately, the patient was fond of rare and raw meat and ate from one to six uncooked pancreases daily, averaging over three. At my suggestion he cut them in pieces about the size of an oyster and bolted the pieces whole.

He began at once to improve, his appetite returned, his strength increased and he gained in flesh. His diet was not much restricted, nothing but sugar was forbidden. In a few days he was out of bed, in two weeks he was out of doors and weighed 164 lb., which was a great gain from his lowest weight. Two weeks later he weighed 180 lb., a gain of 16 lb. in fourteen days. The thirst was lessened. The urine had fallen to 2–3 quarts in twenty-four hours; specific gravity, 1028–1030. It was never found sugar-free.

His health continued to improve, he became strong and ruddy and said that he had never felt better.

He continued to eat pancreas and felt well enough to engage in active business, against my advice.

Early in March, 1897, he ate some stale pancreas, vomited, become disgusted with it and never ate another.

Soon after, his business venture proved a failure and the diabetic symptoms gradually returned, so that in June, 1897, he had lost much of his gain in flesh and strength; urine 7–8 quarts; specific gravity, 1035–38.

About July 1 he developed an enormous carbuncle of the neck and upper part of the back and died July 11, 1897.

An autopsy the following day showed the thoracic and abdominal organs, except the pancreas, normal in gross appearance. The pancreas was represented by a fibrous cord about one fourth the size of the normal gland. Unfortunately, postmorten changes made it impossible to discover anything about the minute changes in the specimen.

I have tried the same treatment in several other cases of diabetes without benefit, but no other patient has been able to eat such a quantity of raw pancreas or continue eating it as long as C. P.

The usual comment on pancreatic feeding in diabetes is that it has been disappointing or useless. This case, my own subsequent experience and the reported

lack of success by others, suggests that the usual failures may be due to giving too little of the pancreatic substance.

Few people would be able to eat, even if they could get, the amount of uncooked pancreas taken by my patient.

About the time C. P. was eating pancreas I was also treating several cases of myxedema by thyroid feeding with the usual striking success.

The result in the diabetic case seemed so simple and natural that it did not then occur to me to publish it.

Now, so far as I know, this case remains unique after a dozen years, and that is my excuse for writing about it at this late day.

## Medical Progress.

### REPORT ON DERMATOLOGY.

BY JOHN T. BOWEN, M.D., BOSTON

#### PROFESSIONAL DERMATITIS OF THE HANDS.[1]

THERE has been much discussion as to the etiology of these affections, and although one important element, that of external irritation, is quite evident, much still remains undecided. By Hebra they were placed in the category of the eczemas, and he considered them due to a lowered power of resistance, either individual or local, to mechanical irritation of any nature. According to this authority, the state of health of the subject at the moment of the application of the eczema-producing cause is important. People who have been able to withstand the effects of an irritant when in good health often succumb to it when their condition is less vigorous.

Kaposi thought that the form of eczema to be produced was due to the nature, intensity and duration of the irritation, as well as to the irritability of the individual skin. The acute or chronic course of the eczema depends on the irritability of the skin and on the single or repeated application of the irritating substance. This irritability of the skin varies in different individuals and sometimes at different times in the same subject. Upon what depends this variability? This question it has been difficult to decide.

Besnier believed that the irritability depended upon external or internal toxic conditions, varying according to the individual. Hallopeau and Leredde consider that there are general and local conditions not well understood, among which they number modifications of the oil secretion of the skin. And, in fact, it is true that a professional dermatitis is rarely seen on the palm of the hand, a place where the perspiration mingled with fatty secretion is abundant, and also that this affection is more common during the winter; and that, finally, oily skins appear to be less affected than dry skins. Thibierge invokes the chemical qualities of the skin, an individual, personal or hereditary predisposition, affected especially by digestive troubles. Others also lay stress on the importance of attention to hygiene, and especially to the digestive system.

The basis of the present paper was offered by the study of 27 cases of professional dermatitis. Of these 27 patients, very few were in perfect health; most of them suffered from some functional disorder, such as migraine, neurasthenia, etc.; 13 of them were affected with digestive troubles, gastralgia, pyrosis, vomiting, etc. A large number had hyperesthesia of the stomach on pressure. Hence the writers agree with Tibierge and Darier that the frequency and, also, without doubt, the importance of digestive troubles were incontestable. The question then arises just what is a digestive trouble, and in this the writers allow themselves a pretty wide range as to the quality and quantity of food and drink that is deemed injurious, as well as the psychical and inhibitory influences that affect digestion. With these premises they come to the conclusion that there was serious vitiation of digestive hygiene in 22 of their 27 patients.

By a method of digestive treatment that the writers call the ataraxic treatment, they found that, of their 27 patients, 14 were improved or cured in an average of ten days, the digestive treatment being combined with local treatment and the suppression of the irritant. In some of these cases patients were cured in a few days who had been afflicted for months and years. In 9 cases the digestive treatment alone was curative without local treatment or the suppression of the irritant. As in 9 cases no digestive trouble could be detected, the writers affirm that it is a vitiation of the digestive hygiene and not a dyspeptic trouble that is pathogenic, a distinction that will probably be difficult of appreciation to many. Much stress is laid on the importance of deliberate mastication, as what the writers call tachyphagia is responsible for some of the professional dermatoses. It is the opinion of the writers that the functional irritation of the stomach caused by vitiation of the gastric hygiene is transmitted by means of the sympathetic and cerebrospinal systems to the vasomotor, secretory and trophic nerve fibers of the skin. Hence the beginning of this form of dermatitis, like so many others, is characterized by pruritus and to some extent dermatalgia, and to this phase erythema, vesiculation and "eczematisation" rapidly succeed.

#### LEPROSY.[2]

At a meeting of the New York Academy of Medicine, Dec. 29, 1910, several interesting papers on this subject were presented.

The first paper was by S. Pollitzer, of New York, and dealt with the history of leprosy in the United States. After a brief sketch of the history of leprosy in Europe, the writer states that at the time of the discovery of America, leprosy was still quite common in Europe, although evidently on the decline, and that it existed to a considerable extent during the next two centuries. The disease being so relatively frequent in Europe during the colonization period of this country, it seems odd that there is no authentic evidence of its occurrence among the early colonists. On

[1] Jacquet et Jourdanet: Ann. de Dermat. et de Syph., January, 1911.

[2] Jour. Cutan. Dis., May, 1911.

the other hand, there is clear evidence of the introduction of the disease into Mexico, South America and the West Indies. Columbia is said to-day to contain at least 30,000 lepers, more than are included in any leper center on this continent. The first authentic mention of leprosy in the United States is found in a book published in 1775 by a Captain Romans on the "Natural History of East and West Florida," in which he describes the disease among the blacks. At that time also the disease existed in Louisiana, brought over by the Spaniards. There has been a great decrease in the number of lepers in Louisiana in the last forty years, the number at the present time being estimated as between 300 and 500.

There is no record of leprosy among the early French settlers in Canada. In 1815 the disease was introduced into New Brunswick by a woman from Normandy, who settled in Tracadie on the Gulf of St. Lawrence. The disease soon after appeared in the family of this woman and among her neighbors, and there are to-day about 20 cases in the asylum in this village. In 1892 some cases were discovered in Cape Breton. In South Carolina 17 cases occurred between 1847 and 1882. Fifteen cases are recorded in Charleston during the last ten years, 5 of whom are now living. Next came the focus of leprosy in Minnesota, which came from the Scandinavian immigrants who settled in large numbers during the middle of the last century in the northwestern states. It is known that there were about 170 of these lepers who had the disease when they left Norway. There are about 30 cases in their descendants now living.

The Pacific coast has been invaded by lepers from the far East and from the Pacific islands. San Francisco has lepers from many countries of the world. Texas and Florida have also of late years furnished their quota of lepers.

Besides these foci of leprosy, cases of the disease are found among the immigrants in almost all of the larger cities. A large number of these cases occur among the Chinese. Dr. Morrow states that he has seen in New York about 150 cases during the last thirty years. Official records of the disease are apt to underestimate the numbers. A careful attempt to estimate the number of cases in this country, made by the Marine-Hospital Service in 1902, gives a total of 278 cases, of which more than half were in Louisiana. Two thirds of these were said to have acquired the disease in the United States. This, according to Pollitzer, is probably less than half the true number in this country.

The second paper, by Dyer, of New Orleans, treated of the sociological aspects of leprosy and the question of segregation. At the present time all the countries of Europe have provided for lepers when discovered, including even Russia. India cares for the children of lepers also, and Japan, where the number of lepers is estimated at 20,000, has all of them segregated. Most of the West Indian islands have provided for leprosy, and in South America a few, not many, of the countries have followed suit. Tracadie in New Brunswick and D'Arcy Island in British Columbia have also made provision. In the Philippines and in Guam, the United States has provided hospitals for over 3,000 lepers.

The United States government has so far done practically nothing. Some of the states have, however, taken legislative action, among them Minnesota, Iowa, Oregon and California. In New York a few lepers have been sent to an island and then allowed to escape. Louisana is the only state that has regularly provided for lepers since 1894. At the State Home for lepers, 200 patients have been admitted in sixteen years, and there are at present nearly 70 inmates. States nearby, such as Mississippi and Texas, have numerous cases which are under no control, and from which the disease has been known to spread to others. The writer emphasizes the fact that segregation is considered essential in almost every country except the United States, and has been endorsed by the European leper congresses, consisting of delegates from almost all the leprous centers. Nevertheless, Congress has refused to consider the question of a national asylum. Dyer considers that such a national asylum for all lepers should be instituted; that not all cases of leprosy, however, need to be segregated, as, for instance, those who have survived the disease and who show only trophic changes and mutilations. In these cases there is no danger to others and no need of isolation treatment for themselves.

In Louisiana almost all the patients go to the home willingly, without need of coercion, influenced partly by the possibility of a cure.

The third paper was by Drs. Duval and Gurd, of New Orleans, on experimental leprosy and its bearing on serum therapy.

The writers regard the cultivation of the leprosy bacillus in pure cultures as an assured fact, although the pure cultures on artificial media are attained with great difficulty. It is necessary to place large quantities of the infected tissue upon the culture medium to insure growth. They claim to have succeeded in getting pure cultures of the leprosy bacillus from the cutaneous nodules in 8 cases of leprosy, in 2 cases from the nasal discharge in leprosy, and from experimental lesions in mice and monkeys. They find that cultures will remain alive and virulent for months under unfavorable conditions, and this explains much not before understood as to the transmission of the disease; why, for instance, the disease appears in houses where a leper has previously lived. They regard direct inoculation as possible, but not the usual mode of transmission. They consider from their investigations that the mucous membrane of the naso-pharynx is the point of entrance of the bacilli, and also the chief source of the spread of the disease.

### CANCER IN TAR WORKERS.[3]

Schamberg, of Philadelphia, read an interesting paper on this subject before the American Dermatological Association at its meeting in Washington. Cancer of the skin has been, as is well

[3] Jour. Cutan. Dis., December, 1910.

known, recognized for a long time as occurring in chimney-sweeps, and in tar and paraffine workers. Schamberg describes 5 cases occurring in men working in a tar factory, one of the largest institutions of its kind in the country.

The first patient, who sought aid because of the distress caused by the skin trouble, was an Irishman forty-five years old, who had for twenty years been engaged in saturating paper with tar at a temperature of 240° F. His hands and arms were constantly covered with coal tar on account of his work, which was that of drawing the wet tar paper through rollers. He had developed his present affection two years before and it had been steadily growing worse. There were red patches on the arms from the elbows to the wrists, varying from a pin's head to a fingernail in size and somewhat keratosic. Slight ulceration was seen when the crusts were removed and there were some scars. There were no lesions on the palms nor above the elbows, and the only other part of the body affected was the scrotum, where there was a large ulcerated lesion indurated at the edge, which was increasing steadily in size. There were also two smaller lesions upon the scrotum which had appeared more recently. There were comedo-like plugs in the follicles of the skin of the proximal phalanges.

Upon visiting the tar works where the patient was employed, about 20 men were examined who had to become besmeared with tar in the manufacture of tar paper. There was in several a mild acneiform eruption of the arms, and some of them stated that they often had outbreaks of "yellow heads" on their arms, which soon disappeared. Four other cases were found which presented the appearances of tar cancer on the hands and arms, mingled usually with keratoses and comedones. These cases of tar cancer seemed to occur usually in those who had reached or passed middle life.

A miscroscopic examination (of Case I) showed a great thickening of the horny layer which projected above the level of the skin. There was a marked hyperplasia of the Malpighian layer, and the epithelial cells showed in many places a perinuclear vacuolation. The blood vessels in the papillary layer of the corium were greatly distended and surrounded with masses of round cells. Epithelial nests snared off are seen in several places, together with horny pearls. There were various cell changes in the epithelial cells, some of them surrounded by clear spaces and containing one or several eosinophilic cells.

Chimney-sweep's cancer was first described by Pott in 1775. The cases are chiefly in England and it seems to be almost unknown in other countries. In nearly all the cases the scrotum was affected, sometimes also the extremities. It is a rare affection and is said to have become less common since an act was passed prohibiting children from cleaning chimneys and since economic conditions have been changed.

Tar and paraffine cancer was first reported by Volkmann in 1873. There is a preliminary stage of an acute character that is characterized by aceniform or larger papules. Often there are confluent nodules and boils. After a few months there is an increased formation of epidermis and an increased secretion of the sebaceous glands. Then a horny thickening occurs, with multiple warty growths that become epitheliomatous. The forearms and the scrotum are the usual seats of these cancerous changes. Three cases of cancer in men who worked in coal briquette factories were reported by Zweig.

Schamberg has tabulated 24 cases of cancer in chimney-sweepers, of which there was cancer of the scrotum in 19; of 22 cases of tar and paraffine cancer, there was cancer of the scrotum in 19. As to the outcome in these cases, it was fatal in 4 of the cases of sweep's cancer, and in 7 of the cases of tar and paraffine cancer; but the result was not known in many of the cases.

As to the degree of malignancy, the tendency to spontaneous involution was a marked feature of the tar cancers. Many of the lesions were mechanically destroyed by the patients themselves. The feeble malignancy of chimney-sweep's cancer used to be emphasized, but a number of deaths have been recorded. On the other hand, tar and paraffine cancer are more likely to prove malignant.

In tobacco juice and smoke there is contained an irritant somewhat similar to that of tar and soot, and this has been considered the cause of some of the cases of cancer of the lips and tongue, especially in the case of youthful patients who chewed tobacco. Hence an analogy has been drawn by Thiersch between the influence of tobacco smoking on the lip and that of tar and soot on the scrotum. Of 98 cases of tongue cancer noted by Andrew, of Glasgow, 88 occurred in males.

It must be admitted that there is some irritant in paraffine, cold tar and soot that after long years has the power of stimulating epithelial growth and causing cancer.

Schamberg suggests that, inasmuch as cancer may follow exposure to the x-rays and to radium, the cancer produced by coal tar may be due to the existence of radio-activity in the latter product, and some slight experimentation of his own points in that direction. Furthermore, as only certain kinds of coal seem to possess this property of epithelial proliferation, it is possible that these kinds only have a radio-active property.

### PERIODICAL FALLING OF THE HAIR — A RARE CASE.[4]

Vignolo-Lutati reports a case of this rare affection which had previously been described by Klotz and Ledermann. In the cases reported by the latter writers, the hair fell during the summer and grew again in the winter. The case reported by Vignolo-Lutati was that of a girl of sixteen years. When only fifteen months old, during the autumn, she presented in the occipital region several round bald areas, similar to alopecia areata, which soon became confluent and extended until the whole scalp had become denuded of hair. In the spring there was a return of the growth,

[4] Monatsh. für prakt. Dermat., 1910, t. 51, p. 304.

so that the scalp was well covered, and since then every year had seen a repetition of the same phenomena, the hair falling in the autumn and growing in again during the spring season. The case was carefully followed for two and one-half years, the phenomena that have been described recurring regularly at the same season. It was noted that at no time were there any inflammatory appearances either clinically or histologically. As to the physical condition of the child, she was well developed but rather anemic. It is difficult to understand what the underlying cause of this peculiar affection may be. It is suggested by the writer that it may be an intermittent trophoneurosis, possibly caused by a toxin of microbic origin, or of unknown nature.

## Reports of Societies.

### AMERICAN UROLOGICAL ASSOCIATION.

Winter Meeting of the New England Branch, Boston Medical Library, March 7, 1911.

*Secretary*, Dr. R. F. O'Neil, Boston.

*Demonstration of Specimens.*

MISPLACED LEFT KIDNEY.

Dr. W. W. Townsend, Rutland, Vt. Through the courtesy of Dr. Stone, our state pathologist, I have the pleasure of presenting a specimen of misplaced left kidney. This kidney was taken from a subject who had been murdered, and the kidneys were being observed in the regular routine of the autopsy. The right kidney was in its normal position, the left was found to be lying below the brim of the true pelvis and to the inner side of the psoas magnus muscle. The bifurcation of the aorta, as you will observe, is also at the brim of the pelvis, and at this point there were thrown off two renal arteries, one of which cuts across the upper pole of the kidney, which gives it the appearance of a lobulated kidney. The bifurcation of the vena cava is below that of the aorta, and the common iliac veins take a circuitous route through the pelvis and finally join the iliac arteries after they have divided into the external and internal branches. The ureter, as shown in this specimen, is of normal length and was cut off close to the bladder, leaving, as you will note, a piece of the bladder musculature attached. Unfortunately, the bladder was not preserved. I show this specimen for its anatomic rather than its pathologic interest.

CALCULOUS HYDRONEPHROSIS.

This other Kidney specimen was likewise taken from an individual in the general routine of a medico-legal autopsy, and is of interest to us as it further confirms the knowledge that we already have that a calculus may exist in a kidney pelvis without producing any subjective or objective symptoms in the individual. The hydronephrosis was occasioned in this instance by the calculus protruding into the ureter, thus obstructing the urinary outflow. When this calculus was discovered by Dr. Stone, he preserved the urine in the bladder, and a microscopical and chemical analysis of the same was absolutely negative. The physician who had attended the individual during his lifetime was present at the autopsy and reported that the man had never complained to him of any renal or bladder symptoms whatsoever.

HYPERNEPHROMA.

Dr. A. L. Chute, Boston. I have two specimens I should like to show: One is of a hypernephroma that shows a large amount of hemorrhage into the growth itself. The tumor tissue is represented by the narrow border, while the large mass is hemorrhage into it. The only symptoms that this mass caused were hematuria and a little colicky pain, due to the passage of clots along the ureter.

CALCULOUS PYONEPHROSIS.

The second specimen is an example of pus kidney due to a stone blocking the ureter. I have opened the pelvis and the stone may be seen blocking it just at the origin of the ureter. Besides this there were two loose stones in the kidney which was simply a large pus cavity. This specimen is from a women who had had six previous operations. The first was for acute appendicitis with abscess. The others were for pain in her left loin and pelvis. This pain persisted until I removed the kidney. It illustrates how easy it is to refer pain arising in a kidney to other organs.

CARCINOMA OF THE KIDNEY AND UPPER END OF URETER.

Dr. Paul Thorndike. This patient, a fragile old lady of seventy-two, had no clinical history up to the time hematuria began, a few weeks ago. Cystoscopy showed a normal bladder. Examination showed a mass in the right kidney region, more prominent in front than from behind. The mass was believed to be a hypernephroma. Operation showed it to be a kidney almost destroyed by hydronephrosis, the latter condition being caused by an obstructing mass of cancer at the upper end of the ureter and practically blocking it. In the cortex of the kidney were secondary metastatic areas of carcinoma spread out in a fan shape and suggesting the similar condition so often found in septic cases. It is very improbable that the cancerous mass at the end of the ureter is primary and that the other masses are metastatic from it, though this might be possible. It is more probable that the primary focus of disease is still undiscovered and lies in some other part of the body.

CANCER OF THE BLADDER.

This stone was found, at operation, embedded in a large thickened indurated mass of tissue, involving the right wall of the bladder. Other stones were loose in the bladder. This stone lay encysted in the bladder wall like a jewel in a ring setting. It was easily removed. A bit of tissue removed from its surrounding proved to be epidermoid carcinoma. It seems an admirable illustration of the fact that the constant irritation of a stone in the bladder may and does lead to the development of cancer.

ATYPICAL HYDROCELE SAC.

This specimen was removed from a middle-aged man supposed to be suffering from simple hydrocele. At operation, two sacs were found; the one the normal hydrocele sac of the tunica enclosing a second sac with a thickened infected wall but containing a bloody fluid. It was at first believed by the pathologists that this second sac was congenital and was taking the place of the epididymis and was perhaps a dilatation of congenital ducts. It is, however, more probable that the second sac was simply an offshot from the first, caused by an inflammatory process due to infection, the infection presumably caused by the use of trocars in tapping the original hydrocele.

### MULTIPLE VESICAL CALCULI.

These fifty-two stones were removed at one sitting, through a suprapubic opening from the bladder of an elderly man. They lay covering the floor of the bladder behind a slightly enlarged prostate, and only eight of them could be seen on cystoscopic examination. Some of them are faceted and all must have existed for a considerable time. They are reported merely because of the rarity of such numbers of stones existing in the bladder at one time.

### SPECIMEN OF HYDRONEPHROSIS DUE TO BLOCKING OF THE PELVIC END OF THE URETER BY A CALCULUS.

DR. F. B. LUND. This specimen is a kidney removed from an Italian twenty years of age who had had attacks of pain in his left side since childhood. The tumor in the side had been felt to come and go and had been diagnosed as hydronephrosis. Blood in his urine indicated a stone in the kidney. We had a rather poor x-ray, which showed, apparently, a stone in the pelvis of the kidney. The specimen, as you see, shows this stone with a nipple-like projection such as that mentioned by Dr. Eisendrath in his discussion. Dilatation of the infundibula and calices of the kidney is evident and the cortex has been at places very much thinned out. The pelvis itself was not dilated to nearly the extent of the rest of the kidney in this case. As will be seen, there are two stones in the calices which did not show in the x-ray. It seemed wiser, in this case, on account of the pathological condition of the kidney to remove the kidney instead of simply removing the obstructing stone. If the latter procedure had been carried out, it is very doubtful whether the other stones would have been found. The patient has made an excellent recovery.

### DISCUSSION.

DR. DANIEL N. EISENDRATH, Chicago. In regard to the specimens that Dr. Thorndike showed, it strikes me that the lymphatic mode of infection would explain that case better than a general infection with metastases. It seems to me that if a patient has a primary growth in the body and a scattering of the carcinomas, causing metastases in the kidney, that there would be more symptoms present. Secondly, from the anatomical standpoint, I do not think we appreciate the mode of conveyance of the infection from the bladder to the kidney. I am just working on this subject experimentally, namely, the anatomical routes which infection takes in traveling from the bladder to the kidneys. It seems to me from examination of this kidney that the explanation would be more plausible from the lymphatics.

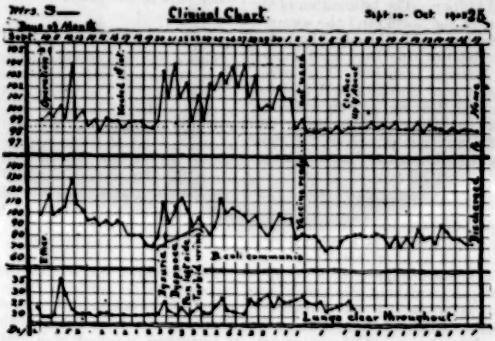
A metastatic carcinoma shows itself in the cortex of the kidney. The renal vessels are terminal arteries and a carcinoma would be deposited in the cortical region. The boundaries would be down in the medullary region. A secondary lymphatic route would explain the case.

Dr. Lund's specimen of hydronephrosis, due to a calculus blocking the outlet of the pelvis at the ureteropelvic junction, emphasizes the point to which Dr. Zuckerkandl, in an article in Vol. 87 of the *Archives für Klinische Chirurgie*, calls attention, namely, that one can very frequently make a diagnosis of the location of such a stone in the uretero-pelvic junction, from the peculiar nipple-like projection which occurs as the result of the calculus becoming wedged into the upper portion of the ureter. In many cases this is easily recognizable in the x-ray picture, such a shadow usually being located opposite either the transverse process of the first or that of the second lumbar vertebra.

Examination of Dr. Lund's specimen will show this peculiar mammary or nipple-like projection, and this was undoubtedly the direct cause of the hydronephrosis.

I would like to ask Dr. Thorndike whether there was any leakage through the ureter in his case?

DR. THORNDIKE. The ureter was not totally obliterated. There was a small amount of blood coming from that ureter. The hydronephrosis contained 6 oz. of fluid. There was probably a little leakage down through.



## REPORT OF CASES.

DR. GEORGE O. CLARK, reported

### A CASE OF COLON BACILLUS BACTERIURIA.

This case is reported to prove that vaccines are not a *sine qua non* in the cure (both clinical and bacteriological) of every bacteriuria.

Sept. 10, 1908, Mrs. S. aged thirty years consulted me for pernicious vomiting of pregnancy and multiple fibroids. I did a supravaginal amputation of the uterus, the only operative procedure which seemed feasible. Convalescence to the eleventh day after operation was smooth and the laparotomy wound healed *per primam*. Suddenly high temperature, pulse and urinary symptoms ushered in an acute left-sided pyelitis. Culture showed the presence of B. coli communis and Dr. Hartwell very kindly prepared an autogenous vaccine. The afternoon of the

vaccine's arrival the patient's temperature had dropped from 102 to normal. The vaccine was not used. During the next two weeks the patient's temperature never went above 90° F. and she was then discharged clinically well.

Two weeks ago, twenty-nine months after operation, I catheterized her ureters and obtained the separate urines. The centrifugalized sediments planted in suitable culture media and incubated showed no growth of bacteria.

Recently, I saw out of town a woman in whom the diagnosis of a supposed pelvic condition was obscure. There was a bacteriuria which was known to the attending physician. He had read of, and was impressed by, the reports of the value of vaccines in the treatment of urinary tract infections, and had been told that urotropin was of no use in certain cases. As he was remote from a laboratory that could prepare vaccines, this particular patient was having no treatment for her bacteriuria.

I feel that if that physician had ever seen a case of bacteriuria treated by vaccines alone, and had then had the further advantage of seeing the same case subjected to the effects of bed, diet, diluents and urinary antiseptics as well, any doubt he had as to the value of these latter would soon have vanished. They must not be ignored; as in this reported case, they may effect a cure while we are waiting for the vaccines.

Dr. J. D. Barney, Boston, read a paper entitled

THE VALUE OF THE GUINEA PIG TEST IN GENITO-URINARY TUBERCULOSIS.

Dr. J. Bentley Squier, New York, read a paper entitled,

SUPRAPUBIC INTRA-URETHERAL ENUCLEATION OF THE PROSTATE.

DISCUSSION.

Dr. Paul Thorndike, Boston. I wish to say a word in connection with the technic of this suprapubic operation. Some years ago I read an interesting paper from the pen of Mr. Fenwick, of London. He advocated a similar procedure to this: A suprapubic enucleation, not beginning in the bladder, but in the prostatic urethra itself.

I quote from Mr. Fenwick's paper, "I submit that our present technic tends, first, to the destruction of the vesical orificial ring; second, to the wholesale destruction of the prostatic urethra with its afferent seminal ducts; third, to the rough manipulation of the membranous urethra." Mr. Fenwick believes that the essential necessity of any technic, whether suprapubic or perineal, is that the vesical orifice must be left intact and covered by its own mucous membrane, and that the objections quoted above will be obviated by using this intraprostatic method of operating.

As to the method of opening the bladder, I think Dr. Squier's point of opening the bladder as high up and as far away from the symphysis as possible is exceedingly well taken. It is often feasible to open the bladder with a horizontal instead of vertical incision and in this way make an incision as high up on the bladder wall as necessary.

I am not of those who persist in using one technic for all prostatic operating and I believe that both the perineal and suprapubic methods of operating have a large field of usefulness. I am much interested in this suprapubic operation and for several reasons prefer the suprapubic route in some cases. In my hands the suprapubic operation has given results which compare favorably with any others I have ever had and I still enucleate prostates frequently by this method.

Dr. B. Tenney, Boston. I do not think that I have anything of special value to add to the admirable paper of Dr. Squier's.

I began with suprapubic operations some ten or eleven years ago with a man who was referred to me with a stone in his bladder.

He was seventy-two years old and had been operated for hemorrhoids and had a lateral lithotomy for stone six years before. He had been entirely dependent on a catheter for five years. After opening the bladder above the pubes the stone was found in a diverticulum and removed. His prostate projected into the bladder and was removed with some difficulty on account of the adhesions from the old lithotomy, but with little bleeding. His recovery was prompt and perfect in every way. Eleven months later he died from anthrax, and I was able to get the bladder for examination.

The internal sphincter had contracted to a ring a quarter inch in diameter and below this was a space the size of my finger, crossed by many bands in its posterior part, and into which the ejaculatory ducts could be traced apparently patent; at least they both allowed the passage of a probe.

The success of that operation was so perfect that it has been my choice ever since, and Dr. Chase and I have lost but one patient, a man whose removed and remaining tissues were malignant and who died of hemorrhage about thirty hours after the operation.

The only suggestion which I can add to the technic so well described by Dr. Squier is to go through between the recti with the bladder empty and then to distend the bladder with water. It will be seen to rise into the operation wound and can be caught and opened without fear of wounding the peritoneum. Some one has suggested that the distention be done with air to avoid flooding the wound with fluid from an infected bladder. I think I shall try this.

In regard to the difference in mortality between the high and low operations, Dr. Chase and I found in a series of over a thousand cases published in 1906 in the *Journal of the American Medical Association*, that the slight excess of mortality for the suprapubic method was due to "shock and hemorrhage." The source of this hemorrhage becomes of interest. There is a rich plexus of veins under the mucous membrane of the bladder and if this be torn up to any extent, or over a considerable area, the bleeding must be free. I have thought that the enucleation downwards, which is the feature of the perineal operations, may be the reason for the less fatal bleeding and have tried to complete the enucleation laterally and downwards before pulling the prostatic masses up. Since making this little change we have had no disturbing hemorrhage.

Dr. F. B. Lund, Boston. We are greatly indebted to the reader for a very interesting paper in which he has brought out many important points. He has demonstrated the ease and rapidity of the suprapubic operation and has mentioned many minor points of importance, such as the tincture of iodine preparation and the importance of keeping the patient dry, etc.

In regard to the choice of routes: The suprapubic route is easier and perhaps quicker. The perineal enucleation of the prostate, however, does not take much more time, and if a man is devoting himself to time, it can be done in four or five minutes. The better way of doing the perineal operation, however, is to dissect down to the prostate and put in a tractor. With a careful anesthetizer, I do not think the few minutes spent in dissection at the perineal route are wasted, and I feel that the urethra is much less torn and the patients do better where the dissection is done carefully and the urethra opened back of the bulb.

I think that downhill drainage is better than uphill.

Occasionally one gets a sinus from the suprapubic operation as mentioned by the reader in connection with making a bladder incision in a place which it would be convenient to sew up. I do believe the perineal operation is safer, that there is less danger from hemorrhage and that with practice it doesn't take very long to do it. In cases with bad lungs it may be well performed under spinal anesthesia. I recently operated on a feeble asthmatic and dissected out the prostate under spinal anesthesia. He suffered no pain except from traction. When he saw me stand up at the close of the operation with a good deal of blood on my apron he was a good deal surpised to see what had been going on. He had as good a convalescence as anybody I ever saw and I feel that spinal anesthesia is a very good resource in prostate cases where general anesthesia is dangerous.

DR. A. L. CHUTE, Boston. Dr. Squier's convincing presentation of his subject has awakened an enthusiasm that I formerly had for suprapubic prostatectomy. I spent some time in London shortly after Mr. Freyer began advocating suprapubic enucleation of the prostate and had the opportunity of seeing a number of these operations at St. Peter's Hospital by Mr. Freyer and his colleagues. On my return I began to do them, but the results were not good. I lost several patients, and while they did not die of hemorrhage, I felt convinced that the bleeding was a factor in the fatal outcome. A part of my mortality I now believe was due to an insufficient appreciation of the importance of a thorough pre-operative renal preparation; a part to the fact that I had several especially poor risks. Disappointed with the suprapubic operation, I turned to the perineal, which I found gave a much lesser mortality, so that I have come to reserve the suprapubic operation for those patients who present large stones. Even in this class of cases it has not been an unqualified success in my hands. For instance in the patient who presented this calculus which weighs about 3 oz., I removed the stone suprapubically, but could not remove the prostate, which was of the small fibrous variety. Later I did a perineal prostatectomy and the patient made a good recovery.

Dr. Squier evidently finds little trouble with the suprapubic removal of these small prostates. The difficulty that I have encountered in this direction has been one of my great objections to the suprapubic operation, though I believe Dr. Squier's technic largely does away with this objection.

It is true that with the perineal operation we may have incontinence, but I believe that this is always due to faulty technic. Instead of opening the membranous urethra, I practically always open the urethra through the tip of the prostate. I believe by so doing one avoids the possibility of direct injury to the compressor urethræ as well as any disturbance of its function that may arise through scar formation, and, therefore, any possibility of incontinence. While there is often incontinence for a time following operation, I know of none of my cases in which this incontinence has been lasting.

It is certainly possible in doing the perineal operation to leave little intravesical tabs, but this again is due to faulty technic, as one should always explore with his finger the region of the bladder outlet to make sure there are no intravesical projections remaining.

I feel that one great advantage of the perineal operation over the suprapubic is the much more definite control of hemorrhage that one has. In the perineal operation you leave everything either tied or packed as a part of the regular routine. In the suprapubic you close up when there is still a pretty free oozing. Usually it stops, but if it does not, as happens in the occasional case, you may have serious trouble.

DR. H. CABOT, Boston. I desire particularly to thank Dr. Squier for his clear, forceful and illuminating paper. While I do not assume that he regards the suprapubic operation as the operation of election for all cases, I am led to believe that he employs it much more commonly than the perineal route. My own experience has led me to believe that there are more or less distinct indications for the selection of one route or the other and that the best practice will employ both operations. Furthermore, it seems to me that in spite of the enormous improvement in surgery in the treatment of this disease, there are still patients who had better be left in possession of their prostates. The selection of these cases depends upon our ability to demonstrate with considerable accuracy the functional capacity of the kidneys. I am not prepared to assert that we have as yet functional tests which are infallible, but I believe that the intelligent use of experimental polyuria and the phenolsulphonephthalein test will enable us to avoid operating upon patients in whom the risk is excessive and whose kidney function may be improved by treatment. In my hands the suprapubic operation has required longer confinement to bed than the perineal method and for patients with poor hearts and kidneys the perineal route seems to me the method of election. The conformation of the prostate should also be taken into consideration. Those projecting chiefly into the bladder are best attacked from above. I am much pleased to hear of Dr. Squier's good results in cases of small hard prostate when attacked from above, for I have not been favorably impressed with the results obtained in these cases when operating from below. The greatest drawback to the suprapubic operation has seemed to me to be the liability to troublesome bleeding, and I shall be interested to try Dr. Squier's method of irrigation in preventing this difficulty. I have seen two cases in which the bleeding did not begin until after the operation was completed and they were so troublesome as to require reopening of the bladder. I have not seen troublesome bleeding following the perineal operation. I agree with Dr. Chute that incontinence following perineal operation is due to faulty technic. It seems to me clear that Dr. Squier's success lies in his unusual skill. Many of the bad results are due to unskillful operating, whereby an excessive amount of time is consumed. It is skillful operating rather than the route selected which will give good results. The perineal operation is more likely to leave bands and tabs of mucous membrane and is, I think, followed by more imperfect results than the suprapubic. On the other hand, I am strongly of the impression that the latter method will be found to show a distinctly higher mortality.

DR. A. MITCHELL, JR., Portland, Me. I am very glad indeed to have had the opportunity of hearing this most interesting paper and discussion. In regard to my experience with suprapubic prostatectomy, my results have been more satisfactory by this method than by the perineal route, and have employed it in the large majority of cases.

I have not been as fortunate as Dr. Squier in so easily controlling hemorrhage after this operation. In a number of instances it has caused me much anxiety, and while I cannot say that I have actually lost a case from hemorrhage alone, it has been a contributory cause. I have been looking for a method of coping with it satisfactorily. While in New York last June I saw Dr. James Pedersen perform a suprapubic prostatectomy. He packed the cavity left by the enucleation of the gland and a portion of the bladder

with long narrow strips of gauze, leaving the ends protruding from the incision; he also employed the usual large drainage tube.

This appeared to me an excellent plan, and I followed it in my cases. In one instance when the bleeding was unusually profuse, the pressure from the gauze strips was not sufficient to control it. The idea came to me that the method sometimes used in checking hemorrhage from the posterior nares might be employed. Accordingly a rubber catheter was passed into the bladder through the urethra and its proximal end drawn out through the incision; after packing the cavity with gauze strips a larger strip was sewn to the catheter; traction was then made on the distal end and the gauze drawn through the incision into the bladder and brought into firm contact with the gauze strips previously introduced; the bleeding was checked very satisfactorily.

I now follow this plan as a matter of routine; having as large a catheter as possible fastened into the urethra before the patient is anesthetized. After the enucleation is accomplished, I do not devote much time in controlling the hemorrhage by hot irrigations, but draw the catheter up through the incision, pack the cavity carefully with the strips of gauze; these are made about an inch and a half wide and several yards long, and are introduced so that they surround the catheter as it lies in the cavity; I also partially fill the bladder at its base with the gauze, a sufficient amount to form a good-sized tampon. I then sew to the catheter a larger strip of gauze, and pull it down into the bladder, guiding it carefully with my finger. Since employing this method have never had difficulty with hemorrhage.

I found in a number of cases the greater portion of the urine drained through the catheter, keeping the patient comparatively dry; so that of late, after removing the gauze, which is usually the third or fourth day after operation, I cut the strip from the catheter, pull it back in the bladder and retain it in the urethra and allow it to drain in a urinal. I have given up the suprapubic drainage tube as it appears to me unnecessary and retards the healing of the wound.

In the last four cases in which I have employed this method of drainage, with the exception of moderate leakage of urine through the gauze strips protruding through the incision, and which ceased after their removal, the patients have been kept dry by the drainage catheter. I regard this as very important, as one of the great drawbacks to the suprapubic operation has been the discomfort to the patient of wet dressings on the abdomen. In the four cases mentioned, two had voluntary urination without suprapubic leakage within ten days and the wounds, skin incision included, were closed in three weeks. I have been fortunate in these cases and do not expect to secure such prompt results uniformly, but feel that the method mentioned is one that will control hemorrhage successfully and in many cases add much to the comfort of the patient by keeping him dry. I shall continue to employ it as it relieves me from the anxiety of post-operative bleeding.

Dr. G. J. Thomas, Rochester, Minn. Dr. Cabot said in his experience he thought the kind of operation depends upon the lesion found in the prostate. This is the rule that we follow at Rochester in doing operations upon the prostate. Dr. Judd, however, prefers to do a perineal operation except in those cases, as stated above, where the suprapubic operation is indicated. We have never, that I know of, seen a permanent case of incontinence from perineal operation.

We have been treating all of our cases before operation. They are given from ten days to two weeks preliminary preparation, which consists of permanent catheter and frequent irrigations of the bladder. We find that certain patients who do not get this preliminary treatment and who show good urinary findings and with the bladder in fair condition, do not do well after operation, so that within the last two months every patient who comes up for operation on the prostate is given this preliminary treatment.

We have also been using the functional tests, which gives us an additional finding as to the condition of the kidneys.

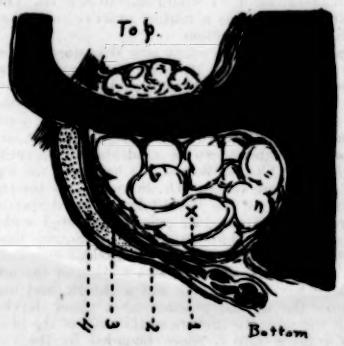
Dr. Townsend. I would like to ask Dr. Thomas whether or not it is a routine practice to cystoscope in all cases of obstruction.

Dr. Thomas. Yes, every case is cystoscoped where it is possible to pass the instruments. If we get a patient who is a very old man, and where the obstruction is very great, we endeavor to pass small catheters and small steel instruments for a short time until we are able to get the cystoscope into the bladder, so that a correct diagnosis can be made before operation.

Dr. G. O. Clark, Boston. It has given me a great deal of pleasure to hear Dr. Squier's very interesting paper and to see the beautifully prepared specimens. There occur to me two points connected with the suprapubic procedure on which Dr. Squier has not touched and to which I should like to call your attention.

If one discards any such idea as that of the normal prostate having a capsule and a sheath, and instead pictures the normal prostate as a gland developing about the prostatic urethra at the neck of the bladder, then growing into a space bounded by the various fasciæ of the region, but, in its relationship to the bladder, covered by little more than mucous membrane, and tunneled by the ejaculatory ducts, one simplifies one's idea of the anatomic relations of the normal prostate.

Microscopically one finds in the normal prostate glandular tissue of two types, elastic tissue, muscle fibers, both striate and nonstriate, vessels, lymphatics, nerves and a skeleton framework of connective tissue supporting these elements. The muscle fibers predominate in the anterior portion of the gland and in the periphery. They have a sphincteric action, and, in the periphery when contracted, serve to empty the glandular ducts of their secretion. Of glands, the two varieties are the submucous or intra-sphincteric, and the more deeply situated forty or fifty lobules comprising the prostatic glands proper, with longer ducts. At the periphery of this glandular mass the smooth muscle tissue and the connective tissue is relatively abundant, and if the normal prostate had a capsule, it would be this tissue which constituted it. But this tissue is not a true capsule; it is the periphery of the gland holding the gland together, and not readily separated from the rest of the gland. In the normal adult the periphery of the gland is in contact with the adjacent fasciæ; in fact, is intimately bound to them and the supporting hammock which they form, for the prostate is in France called "*la loge prostatique.*"



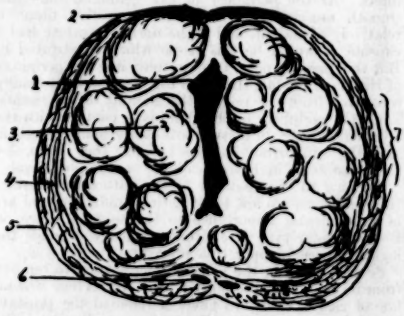
Turning to the anatomy of the pathologic prostate the conditions are apt to be entirely different, and are of fundamental importance to the surgeon, since on the particular type of existing pathology depends the logical choice of operative procedure.

Several times in the morgue I have tried to remove from its hammock the normal prostate. There was no line of cleavage, and to effect a removal the prostate had to be torn out with different tissues adhering. The pathologic small obstructing prostate without glandular enlargement presents a more exaggerated type of this difficulty, and is, I believe, best removed by a perineal rongeuring operation.

Just posterior to the internal meatus may be a second

type of pathologic obstruction — the so-called "third lobe." It is an adenomatous growth upward into the bladder originating in certain glands lying superficially in the prostate just beneath the mucosa or in the mucosa itself. When it is the sole cause of obstruction, it may be easily removed suprapubically. That portion of the prostate lying anterior to the exit of the ejaculatory ducts (in diagram A) very rarely if ever takes part in the obstructive enlargement.

A



AFTER ALBARRAN.

1. Adenomatous "hypertrophy."
2. Lamellæ of compressed tissue — plane of clearage in suprapubic enucleation.
3. Ejaculatory duct.
4. Portion of prostrate not taking part in obstructive "hypertrophy" — left behind.

In those large obstructing prostates, the so-called cases of hypertrophy, there is again definite adenomatous structure. Some of the deep lobules take on a tumor formation, and in growing exert pressure from the interior tending to compress the periphery of the gland against the surrounding resisting fasciæ. Obviously the least resistance is encountered posterosuperiorly. Probably in the early stage of enlargement, the muscle fibers in the periphery of the gland hypertrophy to some extent because of increasing difficulty in doing their work. Subsequently, they undergo a pressure atrophy together with the other portions of the prostatic glandular tissue which do not take part in the tumorous enlargement. Albarran has shown that this tumorous enlargement frequently, almost constantly, originates in that portion of the prostate which lies posterior[1] to the plane of exit of the ejaculatory ducts, and that the portion anterior[1] to this plane rarely ever takes part in the enlargement; on the contrary, it actually atrophies from pressure during the growth of the tumorous mass, and together with the ejaculatory ducts lies outside the obstructing tumor mass. This peripheral portion, once true prostatic tissue, is now seen to be principally fibrous tissue, generally in several lamellæ; partially investing the obstructing tumor mass, readily split apart and giving the zone of cleavage out of which the tumor mass — the so-called hypertrophy — can be so easily enucleated by the suprapubic route. In this suprapubic enucleation, instead of "removing the prostate in its capsule but leaving its sheath," as Mr. Freyer believed, we leave behind, not only the sheath," but the "capsule" as well, together with the ejaculatory ducts and a certain amount of more or less atrophic but non-obstructing prostatic tissue. In this plane of clearage there are no great blood vessels, consequently serious hemorrhage occurs only when, instead of enucleating between these lamellæ, one tries to enucleate between the "capsule" and the "sheath." In a small percentage of cases, not all of the glandular tissue remaining has atrophied beyond hope of repair. In such case, it is possible for some of the patients so operated on to have conserved their sexual potency.

B.

AFTER ALBARRAN.

1. Urethra.
2. Sphincter.
3. Adenomatous "hypertrophy."
4. Peripheral portion, not taking part in obstructive enlargement — lamellated, giving plane of clearage.
5. So-called capsule — containing gland tissue — fibrous tissue — muscle fibers and (7) vessels.
6. Ejaculatory ducts.

These large obstructing prostates (the term "hypertrophy" seems to be an unfortunate misnomer) are, I believe, best removed by the suprapubic route.

DR. J. BENTLEY SQUIER, of New York (closing discussion). In answer to Dr. Thorndike's inquiry regarding the advisability of making a transverse opening at the bladder: I have never made use of it because I have felt that in view of the anatomical relation of the blood vessels such a method of opening the bladder would, theoretically at least, produce more hemorrhage.

In regard to saving the seminal ducts, I think Dr. Clark's discussion covers this point. If the operation is done properly, they should not be injured, and among the specimens which I have shown to-night are a number in which the patients have demonstrated their virility after operation by impregnating their wives. Specimens 239 and 241 are instances of this.

Dr. Tenney's suggestion as to filling up the bladder after the abdominal incision has been made I think is well worth trying.

In regard to hemorrhage following suprapubic intraurethral enucleation, I may say that I have never had a case in which I found it necessary to pack the bladder, and I believe it would be but rarely necessary if the enucleation is carefully carried out so that the prostate is removed from inside the capsule. In a recent conversation with Dr. Haade, of Breslau, he said that in his hospital he removed prostates by the suprapubic route and closed the bladder and suprapubic wound without a drain. An indwelling catheter was placed in the urethra, and following operation more or less continuous irrigation with ice-water of the bladder was instituted. He says that primary union is the rule,

[1] "Anterior" and "posterior" are here used in the relations they bear in Diagram A.

that the ice-water irrigation makes the patient very comfortable and that they never have cases in which severe hemorrhage takes place.

In regard to starting the patient's anesthesia in the operating room, the advantages are set forth by one of the writers of the recent compilation from St. Mary's Hospital, at Rochester. Among his remarks he says that it is much less terrifying to the patient to let him see the large clean room in which he is to be operated upon rather than to start ether in an anteroom, leaving the idea in his mind that he is going into a place of torture.

Also explain to the patient that as he gets very much less ether there is necessarily less danger to himself.

Dr. Lund says, "Then you do get sinuses after suprapubic" operation. Yes, and you get them after perineal. I do not say this from a small experience in prostatectomy. I have done a great many perineal operations. I am not a one-way prostatectomist, but I have proved to my own satisfaction that in operating suprapubically, if the opening in the bladder is made as I have indicated in my paper, there will be fewer long continued fistulæ.

Dr. Lund's criticism that rapidity of operation might necessarily make it a rough one I do not believe is well taken; at least it has not seemed so to me. Some years ago, in a discussion upon prostatectomy, a prominent New York surgeon said that it required great strength to do a suprapubic prostatectomy. This may be true if one simply tears the prostate out, capsule and everything; but an intra-urethral enucleation, properly done, requires comparatively no exertion, as a simple sweep of the finger is all that is necessary to free the prostate.

Dr. Cabot's point that these patients do not do so well if confined to bed for any length of time either before or after operation, I think is a good one. However, there is no reason why a patient who has had suprapubic prostatectomy performed on him cannot be gotten out of bed early. The abdominal wound is in such a position that hernia rarely develops, and if the abdomen is properly supported by adhesive plaster, I believe the danger of this is practically eliminated.

In closing this discussion, I desire to take the opportunity to express to the New England Branch of the American Urological Association my appreciation of their hospitality and of the interest which they have displayed in my paper. While visiting the hospitals in your city I have been impressed with the scientific work which is being done in urology, and feel that the National Society should be very proud of its New England Branch.

## ASSOCIATION OF AMERICAN PHYSICIANS.

### Twenty-Sixth Annual Meeting held at Atlantic City, N. J., May 9–10, 1911.

(Continued from No. 25, p. 896.)

#### EDEBOHLS' OPERATION IN THE TREATMENT OF CHRONIC BRIGHT'S DISEASE.

Dr. James Tyson, Philadelphia: A study of the four cases of nephritis treated by decapsulation reported in this paper shows that in no case was complete cure affected, notwithstanding the healthy appearance of the patients at certain times after operation. However, the operation is so serviceable in certain instances that it ought to be done more frequently. The conditions which demand it are stubborn persistence of symptoms causing great inconvenience or danger of life, such as permanent dropsy, uremia shown by convulsions or intense headache, anuria and large albuminuria. Operation should not be considered until medical treatment proves unavailing. It is also indicated in perinephritis. Contra-indications are an age of over fifty, valvular heart disease with irregularity of action, extensive cardiovascular changes, or albuminuric retinitis.

#### THE TREATMENT OF CHRONIC NEPHRITIS IN CHILDREN BY EDEBOHLS' OPERATION.

Dr. Henry Koplik, New York: The number of cases operated so far is limited; the operation is not curative, but undertaken only in cases in which relief from the symptoms of nephritis has failed by all other means, medicinal and dietetic. The operation itself does not endanger life. The improvement in the symptoms after operation has been striking in spite of the persistence of urinary signs of marked disease of the kidney. The freedom from symptoms is combined with a status of well-being lasting in some of the cases for a period of years. Exposure or indiscretion will not exempt the operated case from recurrence of edema and other symptoms, but the patients, as in one of the cases reported, recovered promptly and remain well for a time, showing that the operation has not crippled the recuperative powers of the kidney.

#### DISCUSSION.

Dr. G. L. Peabody, New York: It is a matter of interest to me to hear these papers. I have had a number of these cases operated on with satisfactory results as a rule. In one case the operation was done four successive times in a period of two years; after each operation a recurrence of symptoms took place with a marked degree of anasarca closing the boy's eyes so that he could not see. After each operation the improvement was marked and lasted for a number of months. He would disappear from the hospital and then come back again with headache, vomiting and almost complete suppression of urine, and in four instances the symptoms were relieved by removing the capsule which reformed after each operation.

Dr. James Tyson, Philadelphia: I want to add to what Dr. Koplik has said that I do not wish to give the impression that the recovery was always prompt. It was quite delayed in two cases, but it occurred nevertheless. A marked symptom following operation was enormous diuresis, going to show that something must have been occurred consequent on freeing the kidney from pressure or obstruction.

Dr. Lewis A. Conner, New York: In regard to the acute cases I would report one case of severe bichloride poisoning with complete anuria, in which it seemed to me the splitting of the capsule might be justified. There was absolutely no impression made upon the kidney by the operation. That bears out Dr. Koplik's contention that the acute cases are not necessarily the most favorable.

Dr. Tyson: In regard to operating upon the two kidneys: It has been questioned whether there is any advantage in operating upon the two kidneys. In the first and perhaps the most prominent of my cases the kidney was operated on. Four weeks later the second kidney was operated on, but without any particular improvement.

#### FEVER, ITS NATURE AND SIGNIFICANCE.

Drs. Victor C. Vaughan, James G. Cumming and John H. Wright, Ann Arbor, Mich.: In August, 1909, Vaughan, Wheeler and Gidley published in the *Journal of the American Medical Association* a preliminary article upon the subject of protein fever.

In that paper it was shown that continued fever with charts closely simulating those of typical fever can be induced in rabbits by repeated subcutaneous injections of egg-white and certain other proteins; this work has been continued, and it has been demonstrated that by varying the dose and the intervals between doses one can induce an acute, an intermittent, a remittent or a continued fever in rabbits by injections of foreign protein. Furthermore, it has been shown that by repeated intra-abdominal injections of various bacteria, acute fever, followed by immunity, will be produced. The authors will hold that fever results from the parenteral digestion of proteins, and that fever must be regarded as a conservative process, although, like many of nature's processes, it often leads to disaster. Its purpose is the disposal of foreign, dangerous material, and, therefore, it must be regarded as beneficent.

DISCUSSION.

DR. S. J. MELTZER, New York: Do you mean by fever only heat production, or is it meant to include the entire complex, that is the heat dissipation, the effect upon heart beat, the effect upon respiration, etc.?

DR. VAUGHAN: Fever is simply one of the effects of digestion. Increased elimination of nitrogen and salts are other effects. whenever a digestive organ is active there is hyperemia. Whenever a large part of the body is sensitized and elaborating ferment there is an increased destruction of tissue and a consequent increase in respiration. Low temperature as well as high temperature may result from this process. When the protein is broken up so rapidly that the poisonous substances are formed in large amount then the result is low temperature.

THE FUNCTIONAL DIAGNOSIS OF DISEASES OF THE PANCREAS.

DR. WILDER TILESTON, New Haven, Conn.: This paper deals with the results of examination of the stools, of absorption experiments, and of various functional tests in six cases of closure of the pancreatic ducts. The value and frequency of macroscopic masses of fat in the stools as a diagnostic sign. Effect of the administration of large doses of hydrochloric acid with pepsin in a case where the gastric and pancreatic sections were both deficient. Remarks on the diagnosis of insufficiency of the external secretion of the pancreas and its causes.

DISCUSSION.

DR. JOSEPH H. PRATT, Boston: I have carried on metabolism experiments in a number of cases in which obstruction of the pancreatic duct was suspected, and in two cases we were able to verify our diagnosis at autopsy and in one case a cancer at the head of the pancreas was found, and I have made observations on one case in which the fecal contents were obtained at the autopsy. One of my cases was the same one studied by Dr. Tileston and my analysis agreed with his. I came to some conclusions which possibly differ from his.

DR. T. C. JANEWAY, New York: I observed last year a case of a young man with true pancreatic diabetes, that is, diabetes with enormous fat stools and all the evidences of gross destructive of disease of the pancreas. The attempt to treat with pancreagen was unsuccessful. I then resorted to the use of raw pancreas. The patient is taking half an ounce of raw pancreas with good effect on his diabetes and has gained greatly in weight and strength, and, though he looked as though he would die in a few weeks, we have been able to greatly better his condition.

*(To be continued.)*

## Book Reviews.

*Annual Report of the Surgeon-General of the Public Health and Marine-Hospital Service of the United States.* For the Fiscal Year 1910. Washington: Government Printing Office. 1911.

Following close upon the report for 1909 (which was reviewed on page 463 of the issue of the JOURNAL for March 30, 1911) comes this report for the succeeding year, dated Jan. 20, 1911, and describing the operations of the Public Health and Marine-Hospital Service from July 1, 1909, to June 30, 1910. Many of the same activities are noted as in the previous report, and in addition particularly the work done in research on cancer, pellagra and anterior poliomyelitis. There is the usual appendix of tabulated statistics. In stating the needs of the Service, Dr. Wyman, the Surgeon-General, reiterates the necessity of a larger appropriation for the printing and distribution of publications, and particularly urges legislation providing an increase of pay for the commissioned medical corps.

*Bismuth Paste in Chronic Suppurations.* Its Diagnostic Importance and Therapeutic Value. By EMIL G. BECK, M.D., Surgeon to the North Chicago Hospital, Chicago, Ill. With an Introduction by CARL BECK, M.D., and a Chapter on the Application of Bismuth Paste in the Treatment of Chronic Suppuration of the Nasal Accessory Sinuses and the Ear by JOSEPH C. BECK, M.D. With eighty-one engravings, nine diagrammatic illustrations and a colored plate. St. Louis: C. V. Mosby Company. 1910.

Beck states frankly in his preface that the development of the use of bismuth paste is not yet complete, but that its value as an aid in certain surgical procedures, both for diagnosis and treatment, has proven so great that his friends have prevailed upon him to publish the result of his researches.

Well-informed surgeons are aware that the use of bismuth paste has become widespread and popular during the past three or four years. Especially is it effective when injected into sinuses and cavities to serve as an x-ray obstructive, so that through its use we are now able to map out accurately the position of cavities regarding which our knowledge formerly was mainly guesswork. Furthermore, as is well known, bismuth paste is often an efficient surgical dressing. The writer devotes sixteen chapters to the various phases of his subject, and illustrates his writing by eighty-one excellent figures. We regard the book as timely. It corrects many false conceptions regarding the employment of the paste, and suggests many novel and interesting uses. We recommend it especially to surgeons and hospital residents.

## PROPOSED AMENDMENT OF PURE FOOD AND DRUG LAW.

IN the issue of the JOURNAL for June 8, we commented editorially on the decision recently rendered by the United States Supreme Court relative to the applicability of the present pure food and drug law to statements as to the supposed or alleged curative properties of proprietary medicines. Shortly after this decision, an act amending the law was introduced before the national House of Representatives; and last week the matter was made the subject of a message from President Taft, which was transmitted to Congress on June 21. This message seems a document which deserves republication, not only for its summary of the history and results of the pure food and drug act, but for its clear and critical statement of fact and argument in the case.

TO THE SENATE AND HOUSE OF REPRESENTATIVES.

"Your attention is respectfully called to the necessity of passing at this session an amendment to the food and drug act of June 30, 1906, which will supplement existing law and prevent the shipment in interstate and foreign commerce and the manufacture and sale within the Territories and the District of Columbia of worthless nostrums labelled with misstatements of fact as to their physiological action — misstatements false and misleading even in the knowledge of those who make them.

"On June 30, 1906, after an agitation of twenty years, the food and drugs act, passed by the Fifty-ninth Congress, received the approval of the President and became law. The purpose of the measure was two-fold — first, to prevent the adulteration of foods and drugs within the jurisdiction of the Federal Government, and, second, to prevent any false labelling of foods and drugs that will deceive the people into the belief that they are securing other than that for which they ask and which they have the right to get.

"The law was received with general satisfaction and has been vigorously enforced. More than 2,000 cases have been prepared for criminal prosecution against the shippers of adulterated or misbranded foods and drugs, and seizures have been made of more than 700 shipments of such articles. More than two-thirds of these cases have been begun since March 4, 1909. Of the criminal cases, more than 800 have terminated favorably to the Government, and of the shipments seized, more than 450 have been condemned and either re-labelled or destroyed. In every case in which the food seized was deleterious to health, it was destroyed. A large number of cases are now pending.

"The Supreme Court has held in a recent decision (United States vs. O. A. Johnson, opinion May 29, 1911) that the food and drugs act does not cover the knowingly false labelling of nostrums as to curative effect or physiological action, and that inquiry under this salutary statute does not by its terms extend in any case to the inefficacy of medicines to work the cures claimed for them on the labels. It follows that, without fear of punishment under the law, unscrupulous persons, knowing the medicines to have no curative or remedial value for the diseases for which they indicate them, may ship in interstate commerce medicines composed of substances possessing any slight physiological action and labelled as cures for diseases which, in the present state of science, are recognized as incurable.

"An evil which menaces the general health of the people strikes at the life of the nation. In my opinion, the sale of dangerously adulterated drugs, or the sale of drugs under knowingly false claims as to their effect in disease, constitutes such an evil and warrants me in calling the matter to the attention of the Congress.

"Fraudulent misrepresentation of the curative value of nostrums not only operate to defraud purchasers, but are a distinct menace to the public health. There are none so credulous as sufferers from disease. The need is urgent for legislation which will prevent the raising of false hopes of speedy cures of serious ailments by misstatements of fact as to worthless mixtures on which the sick will rely while their diseases progress unchecked.

"At the time the food and drugs act was passed, there were current in commerce literally thousands of dangerous frauds labelled as cures for every case of epilepsy, consumption and all lung diseases, cures for all kidney, liver and malarial troubles, cures for diabetes, cures for tumor and cancer, cures for all forms of heart disease; in fact, cures for all the ills known at the present day.

"The labels of many of these so-called cures indicated their use for diseases of children. They were not only utterly useless in the treatment of the disease, but in many cases were positively injurious. If a tithe of these statements had been true, no one with access to

the remedies which bore them need have died from any cause other than accident or old age.

"Unfortunately the statements were not true. The shameful fact is that those who deal in such preparations know they are deceiving credulous and ignorant unfortunates who suffer from some of the greatest ills to which the flesh of this day is subject. No physician of standing in his profession, no matter of what school of medicine he may belong, entertains the slightest idea that any of these preparations will work the wonders promised on the labels.

"Prior to the recent decision of the Supreme Court, the officers charged with the enforcement of the law regarded false and misleading statements concerning the curative value of nostrums as misbranding, and there was a general acquiescence in this view by the proprietors of the nostrums. Many pretended cures, in consequence, were withdrawn from the market, and the proprietors of many other alleged cures eliminated false and extravagant claims from their labels, either voluntarily or under the stimulus of prosecution. Nearly one hundred criminal prosecutions on this charge were concluded in the Federal Courts by pleas of guilty and the imposition of fines. More than 150 cases of the same nature involving some of the rankest frauds by which the American people were ever deceived are pending now, and must be dismissed.

"I fear, if no remedial legislation be granted at this session, that the good which has already been accomplished in regard to these nostrums will be undone and the people of the country will be deprived of a powerful safeguard against dangerous fraud. Of course, as pointed out by the Supreme Court, any attempt to legislate against mere expressions of opinion would be abortive; nevertheless, if knowingly false misstatements of fact as to the effect of the preparations be provided against, the greater part of the evil will be subject to control.

"The statute can be easily amended to include the evil I have described. I recommend that this be done at once as a matter of emergency."

Since the receipt of the above message, another bill amending the pure food and drugs act in accordance with the President's recommendations, has been introduced into the United States Senate.

## CARE AND PREVENTION OF BLINDNESS.

THE eleventh annual convention of the American Association of Workers for the Blind was held last week at the Pennsylvania Institution for the Blind, in Overbrook, near Philadelphia. The opening session on June 23, which was attended by over 300 delegates representing 30 states of the Union, was devoted to the topic, "Recent Experiments in the Employment of the Blind." Extensive exhibits on this subject were made by the Massachusetts and New York Commissions for the Blind. Mr. James J. Daw, of Minneapolis, Minn., read a paper on "Summer Schools for Blind Men." In his address before the evening session, Mr. Jacques Koloubovsky, director of the Princess Marie Alexandrovna Society for Promoting the Welfare of the Blind in Russia, stated that, according to the latest universal Russian census, there are in that country 247,900 blind persons, representing a rate of 19.7 to every 10,000 of population in the empire. This high relative proportion of blindness is largely due to the dense ignorance of the people and to the prevalence among them of ophthalmia neonatorum.

In this connection we wish to call attention to a monograph, of which we have received an advance copy, on "The Prevalence and Prevention of Ophthalmia Neonatorum in Ten Massachusetts Cities." This paper, which is the first of a series to be published by the American Association for the Conservation of Vision, is written by Mr. Henry Copley Greene, of Boston, with a preface by Dr. F. Park Lewis, of Buffalo, N. Y., and represents the results of a study undertaken by the Research Department of the Boston School for Social Workers. The JOURNAL has already made frequent previous comment on the prophylaxis of gonorrheal ophthalmia, and has recently published an editorial on this subject in its issue for Feb. 9. The present monograph by extensive tabulation of statistics corroborates the statements therein made. It is a valuable piece of lay research, and constitutes an excellent exposition of the most important problem involved in the prevention of blindness.

## OPENING OF THE FLOATING HOSPITAL SEASON.

THE annual season of the Boston Floating Hospital opens this week, the first trip being made on Thursday, June 29. This year for the first time it is planned that the hospital boat shall make two excursions every twenty-four hours instead of one, as previously. Except in stormy or very foggy weather, a day trip will be made from 9 A.M. to 4.30 P.M., and a night trip from 7.30 P.M. to 6 A.M. This extension of the work done by the hospital, will require an increase in the number of nurses from 60 to 70. The staff of visiting physicians will be the same as last year. Dr. Edward A. Knowlton will be the acting resident physician, and Dr. Arthur I. Kendall will have charge of the bacteriologic laboratory.

In its announcement, the Board of Trustees states that during the season of 1910 "462 different permanent patients received care for an average of 16 days of 24 hours each, or a total of 7,519 full days' service; 984 day patients made 5,702 day trips; mothers who accompanied their sick children and received instruction in nursing, helping in their care, made 5,649 day trips; 798 day trips were made by well children too small to be left at home by their mothers. This represents a service to the beneficiaries of this work of a total of 19,868 days for the summer of 1910."

The established value of this hospital, not only for charitable service to the poor but as a training-school for nurses and physicians, makes it worthy of cordial encouragement; and it is sincerely to be hoped that its plans for increased usefulness during the coming season may meet with deserved success.

## EXPERIMENTAL MEASLES IN THE MONKEY.

In the issue of the JOURNAL for June 15, we commented on the recent work of Drs. Anderson and Goldberger on "Experimental Measles in the Monkey." In a supplemental note in the weekly report of the United States Public Health and Marine-Hospital Service for June 16, these authors describe their investigation in somewhat greater detail, and announce their further conclusions that the susceptibility of rhesus monkeys to inoculation "with measles with blood from a human case appears at best not to be very great and is subject to considerable individual variation"; and that "the virus of measles gives no visible growth in standard glucose broth in a fermentation tube." All attempts to demonstrate or cultivate the infecting etiologic agent in measles have thus far been unsuccessful.

## MEDICAL NOTES.

PROPOSED ABOLITION OF ABSINTHE IN FRANCE. — Report from Paris on June 15, states that a bill has been introduced before the French Senate prohibiting the manufacture and sale of absinthe in France.

AMERICAN SOCIETY OF TROPICAL MEDICINE. — At the recent meeting of the American Society of Tropical Medicine in New Orleans, La., Dr. Joseph H. White, of the United States Public Health and Marine-Hospital Service, was elected president of the society for the ensuing year.

A CENTENARIAN. — Mrs. Lucy S. Hicky, of Herring Cove, Nova Scotia, died last week in Gloucester, Mass., at the reputed age of one hundred and three. She had been bed-ridden for a number of years. She is survived by one son.

A TENNESSEE DWARF. — Joseph A. Carter, who died last week in Jefferson County, Tennessee, at the age of seventy-three, was reputed to be the smallest adult in that state. He is said to have been only 42 inches in height and to have weighed only 58 lbs. He was presumably a cretin.

CONVICTION FOR OPIUM SMUGGLING. — Report from Binghamton, N. Y., states that on June 23, before the Federal Court in that city, Walter L. Funk was convicted of having smuggled over $100,000 worth of opium across the Canadian border into this country, and was sentenced to four years' imprisonment and a fine of $20,000.

GRADUATION AT LAKESIDE HOSPITAL TRAINING SCHOOL. — On Thursday, May 11, was held at Cleveland, Ohio, the eleventh commencement of the Lakeside Hospital School for Nurses. Diplomas were awarded to thirty candidates. The address to the graduating class was made by Dr. Charles M. Green, of Boston, on "The Personality of a Nurse as a Factor in her Success."

LECTURES BY DR. HRDLICKA. — On June 27, Dr. A. Hrdlicka, of the Smithsonian Institution, Washington, D. C., delivered an address on "The Evolution of Human Teeth and their Racial Differences," before the Alumni of the Dental Department of the University of Buffalo, N. Y. A similar lecture was given by Dr. Hrdlicka on May 25 before the Maryland State Dental Association, at Baltimore, and on June 1, before the Ontario Dental Society, at Toronto, Canada.

INCREASE OF SALARY FOR PUBLIC HEALTH SURGEONS. — Report from Washington, D. C., states that on June 20 the United States Senate passed a bill raising the salaries of surgeons in the Public Health and Marine-Hospital Service as follows:

"The pay of the surgeon-general is raised from $5,000 to $6,000; assistant surgeon-generals from $2,900 to $4,000; senior surgeons from $2,500 to $3,500; surgeons from $2,500 to $3,000; passed assistant surgeons from $2,000 to $2,500, and assistant surgeons from $1,600 to $2,000."

NORTH AMERICAN SANATORIUM FOR SURGICAL TUBERCULOSIS. — The issue of the Philadelphia *North American* for June 20, contains an announcement of the reopening of the North American Sanatorium for the Treatment of Sur-

gical Tuberculosis, in Ventnor, Atlantic City, N. J. This institution is the direct successor of the North American Sanatorium for Convalescent Children, which had been in operation for the past nine years.

"While this institution was founded only with a general view to benefiting poor children, little by little its destined purpose became more clearly defined to those directing it. Eight years of dealing with convalescents led gradually to the specific purpose which was shown as the mission most needed — ministering to children crippled by tuberculosis. In 1909 the sanatorium, after having cared for more than a thousand convalescents in its eight years of service, was restricted to the exclusive use of poor children suffering from surgical tuberculosis."

The new sanatorium will be under the direction of an executive committee consisting of Dr. H. Augustus Wilson, Dr. John B. Carnett, and Dr. William L. Rodman, all of Philadelphia, representing respectively the Jefferson, the University, and the Medico-Chirurgical Hospitals. The resident surgeon is to be Dr. John C. Tull, of Atlantic City; and there will be a large consulting staff of physicians and surgeons from Philadelphia, from Atlantic City, and from Camden, N. J.

NATIONAL ASSOCIATION FOR PREVENTION OF TUBERCULOSIS. — The seventh annual convention of the National Association for the Study and Prevention of Tuberculosis was held last week in Denver, Colo. The annual address, at the opening session on June 21, was made by the president, Dr. William H. Welch, of Baltimore. Addresses were also made by Mr. Edward F. McSweeney, chairman of the board of trustees of the Boston Consumptives' Hospital, on "The Relation of Tuberculosis to the Cost of Living"; by Dr. M. P. Ravenel, director of the Wisconsin State Hygienic laboratory, on "Human Infection with Bovine Tuberculosis"; by Dr. George J. Nelbach, of New York, on "Anti-Tuberculosis Organization"; and by Dr. Edwin A. Locke, of Boston. Among the new directors elected at the business meeting were Dr. James H. Miller, of New York, and Dr. Vincent Y. Bowditch, of Boston. The following resolutions were unanimously adopted by the Association:

"*Whereas*, the care of advanced cases of tuberculosis has been found from experience to be particularly difficult in institutions located at considerable distance from the home of the patient, and

"*Whereas*, the municipality and the county have in most cases been found to be satisfactory units for the care of advanced cases; and

"*Whereas*, the stamping out of tuberculosis depends so largely upon the segregation of advanced cases; therefore be it

"*Resolved*, That the National Association for the Study and Prevention of Tuberculosis approves a plan whereby municipalities and counties shall be encouraged to erect satisfactory institutions for the treatment of advanced cases; and further,

"*Resolved*, That this Association approves a plan whereby municipalities and counties shall be encouraged to establish dispensaries for the discovery, treatment and prevention of cases of tuberculosis."

## BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, June 27, 1911, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 29, scarlatina 21, typhoid fever 10, measles 91, smallpox 0, tuberculosis 69.

The death-rate of the reported deaths for the week ending June 27, 1911, was 13.54.

BOSTON MORTALITY STATISTICS. — The total number of deaths reported to the Board of Health for the week ending Saturday, noon, June 24, 1911, was 177, against 178 the corresponding week of last year, showing a decrease of 1 death, and making the death-rate for the week, 13.40. Of this number 94 were males and 83 were females; 174 were white and 3 colored; 110 were born in the United States, 61 in foreign countries and 6 unknown; 42 were of American parentage, 112 of foreign parentage and 23 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 37 cases and 2 deaths; scarlatina, 27 cases and 0 deaths; typhoid fever, 15 cases and 1 death; measles, 97 cases and 4 deaths; tuberculosis, 66 cases and 23 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 14, whooping cough 2, heart disease 19, bronchitis 3. There were 15 deaths from violent causes. The number of children who died under one year was 32; the number under five years, 47. The number of persons who died over sixty years of age was 52. The deaths in hospitals and public institutions were 79.

SENTENCE FOR USING COCAINE. — Before the Municipal Court in Boston last week, a resident of this city was sentenced to six months in the House of Correction for having cocaine in his possession.

Bequest to Free Home for Consumptives. — The will of the late James D. Casey, which was filed for probate last week in the Norfolk County Court at Dedham, Mass., contains a bequest of $300 to the Free Home for Consumptives, Quincy Street, Dorchester. A "country holiday festival" for the benefit of this institution was held in Boston on June 24.

Industrial School for Deformed Children. — At the annual graduation exercises, on June 22, of the Industrial School for Crippled and Deformed Children, Boston, diplomas were presented to six pupils by Dr. James S. Stone, of this city, who also announced that the trustees of the institution have purchased land adjacent to the present building for the purpose of future enlargement of the school.

Commencement at Yale. — At the annual commencement of Yale University last week, the honorary degree of Sc.D. was conferred on Dr. William H. Howell, of Baltimore, dean of the Johns Hopkins Medical School, and professor of physiology at that institution. The annual address to the graduating class of the Yale Medical School was made by Dr. Walter B. Cannon, of Boston, on "The Career of the Scientific Investigator."

Open-Air School for Children. — The Women's Municipal League of Boston announces that its Committee on Open-Air Schools "is again planning to hold an open-air school at Castle Island through July and August of this summer, hoping to start with an enrolment of two hundred children, now being selected for this purpose by Dr. Harrington, physical director of public schools. These children are from seven to eleven years old, and will be under the supervision of the same head teacher as last year." To meet the expenses of this school, the sum of $2,000 will be needed, and the committee makes urgent appeal for subscriptions to this amount.

Annual Meeting of Maine Medical Society. — The annual meeting of the Maine Medical Society was held at Augusta, Me., on June 28 and 29. There were morning and afternoon sessions on both days. Following the afternoon session on June 28, the members were entertained on the annual outing as guests of the Kennebec County Medical Society. Among the papers read at the afternoon session on June 29 was one by Dr. Charles L. Scudder, of Boston, on "The Surgical Treatment of Gastric Ulcer." The annual banquet of the society was held on the evening of June 29, and following it the annual oration was delivered by Dr. Henry A. Christian, of Boston, on "Modern Methods of Clinical Investigation in Relation to Hospital Organization."

### NEW YORK.

New Tuberculosis Hospital in Poughkeepsie. — A new hospital for tuberculous patients has recently been erected in Poughkeepsie, N. Y. with the sum of $50,000 which was raised largely by the Young Women's Christian Association of that city.

Junior Sea Breeze. — The "Junior Sea Breeze," at which sick babies and their mothers are cared for in tents, was opened for the season on the grounds of the Rockefeller Institute, 64th street and the East River, on June 19. This camp, with an efficient corps of physicians and trained nurses, is conducted, like "Sea Breeze" at Coney Island, by the New York Association for the Improvement of the Condition of the Poor.

Recent Honorary Degrees. — Among the New York men upon whom honorary degrees were conferred at recent university commencements were the following: Prof. Veranus A. Moore, of Cornell University, head of the Veterinary Department of New York State, Doctor of Veterinary Medicine by the University of Pennsylvania; Dr. William Warner Hoppin, of New York, Doctor of Literature by Brown University.

Trial of a Christian Science Healer. — Wentworth B. Winslow, the Christian Science healer who some time ago was arrested at the instance of the County Medical Society on the charge of practising medicine without a license, was on June 19 held by Magistrate Kernochan for trial in the Court of Special Sessions. In his brief Mr. Vandiver, counsel for the society said, "The practice of belief in Almighty God and in the religious tenets of the churches has never been construed by any court in America to be a business, a vocation, a profession; nor has any court in America ever countenanced pseudo-religious practices in defiance of established law. The defendant was neither conducting an eleemosynary institution nor a church; he was neither preaching nor teaching; he was not in the sanctuary of the faith. On the contrary, he was in a suite of offices in an office building, with his name on the door, conducting the business of receiving

all comers, and selling them an intangible something for tangible specie. This was not religion; it was business. Similar business might be opened by anyone under the pretense of carrying out the tenets of a religious faith." The magistrate, in announcing his decision, expressed his full concurrence in the opinion declared by Magistrate Freschi in the similar Cole case, that the practice of Eddyite healing for money is a violation of the law in New York State.

6. SOLOMON, M. *Report of a Pronounced Case of Splenomyelogenous Leukemia with Autopsy.*
7. *HUFFMAN, O. V. *The Etiology of Epidemic Poliomyelitis and Its Possible Relation to Beriberi.*
8. FERNANDEZ, F. M. *The Distribution of Trachoma in Cuba. With Notes in Regard to a New Procedure in the Treatment.*

7. Huffman writes a suggestive paper on the etiology of epidemic poliomyelitis and draws some striking comparisons between this disease and beriberi (epidemic polyneuritis). Seaports, he says, are usually the focus for epidemics, but inland epidemics may follow. It may be that the virus is spread by a mosquito or insect imported from the tropics with fruit. The incidence of poliomyelitis in domestic animals should make us suspect food. For many years beriberi has been associated with a diet of rice. The fact that the epidemic of poliomyelitis in New York in 1907 was preceded by a visit of Brazilian warships with beriberi present among the crew might be significant. We are accustomed to consider neuritis very distinct from any lesion in the cord, yet the axis cylinder process in the nerve and the cell body in the cord are one cell — the neuron. [L. D. C.]

### NEW YORK MEDICAL JOURNAL.

JUNE 10, 1911.

1. BISHOP, L. F. *A Review of Methods of Examination in Heart and Blood-Vessel Diseases, with Special Reference to the Discovery of Therapeutic Indications.*

9. LOURIA, L. *Acute Hematogenous Infections of the Kidney and Pyelitis of Pregnancy. Their Medical Treatment.*

6. Clark makes a preliminary report on an electrical method whereby abnormal tissue may be destroyed by rapid depletion of its fluid element. He states that a specialized static current is capable of producing superficial or deep destruction of tissue by desiccation. This current has sterilizing, deodorant, styptic and stimulating properties. It has no particular affinity for abnormal tissue, but the size of the area of destruction can be easily controlled. It is operative in all accessible lesions and works from without inward. [L. D. C.]

2. Pfahler finds that the adhesions formed in gall-bladder disease often cause definite displacement of the stomach and duodenum which is recognizable by means of the x-ray and a bismuth meal. The evidence of adhesions is best obtained by fluoroscopic view in the upright position, in which the errors of pressure may be eliminated, but plates should also be made for record and detailed study.

3. Nathan finds that patients with arthritis deformans, who have failed to improve under the recognized method of treatment, often get marked improvement from the continued use of thymus extract given in 5-gr. doses three times a day. If taken for a long time marked improve

ment if not cure results. He is unable to explain its action. General nutrition first begins to improve, perhaps after a month's treatment and this is followed by relief from pain and relief from disability.

9. Cole and Winthrop, treating twenty-one cases of pellagra in all stages and types of the disease with salvarsan, find only 33.3% of improvement, lasting seven or more days. The authors feel that this treatment offers no better result than other forms.

14. Morris believes that the sudden breaking open of abdominal wounds after gastric operation, which is often witnessed, is due to trophic or neurovascular disturbance associated with sensory nerve disturbance in the stomach zone of head. [E. H. R.]

### The Lancet.

#### May 13, 1911.

1. *Mott, F. W. *A Lecture on Heredity and Insanity.*
2. *Windle, J. D. *An Address on Abnormal Forms of Breathing in Cases of Angina Pectoris with Pulsus Alternans.*
3. *Bonney, V. *Six Cases of "Utriculoplasty" for Uterine Hemorrhage, one of which was followed by Pregnancy and Labor.*

6. Branson, W. P. S. *Some Unusual Effects of Perforated Gastric Ulcer.*
7. Walker, C. E. *Progress in Cancer Research: a Note on Work in the Research Department of the Glasgow Cancer Hospital.*
8. Forrester, G. P. *The National Insurance Scheme: the Prussian Official Tariff for Medical Attendance.*

1. Mott, in a lengthy article on heredity and insanity, draws the following conclusions, among others: (*a*) It is the tendency to nervous and mental disease which is inherited. (*b*) Alcohol may help but of itself is not the main cause. (*c*) Certain types of insanity may be transmitted with greater frequency than others. (*d*) Mothers transmit insanity far more frequently than do fathers.

2. Windle discusses the "pulsus alternans," pulsus bigeminus, transient and continuous dyspnea, paroxysmal dyspnea, "inverted" and "periodic" forms of breathing and the Cheyne-Stokes breathing as these phenomena occur in angina pectoris. The paper is profusely illustrated with numerous tracings.

3. In those conditions known as chronic fibrostic metritis, etc., associated with persistent bleeding and usually treated by hysterectomy, Bonney believes that the simpler operation of utriculoplasty may be used to advantage. This operation consists of excising a wedge-shaped piece out of the fundus of the uterus and then sewing the remaining halves together so as to form a small miniature uterus. [J. B. H.]

#### May 20, 1911.

1. *Pasteur, W. *Post-Operative Lung Complications.*
2. Savage, G. H. *Mental Disorders and Suicide.*

4. Finzi, N. S. *The Radium Treatment of Cancer: Experiences of over One Hundred Cases.*
5. Hutchinson, T. *Diffuse Lipomata and Animals: Pubic Lipomata in Man and Nuchol Lipomata in Man and Animals.*
6. Davies, F. C. *A Case of Thrombosis of the Superior Vena Cava and Great Veins.*
7. Corner, E. M. *Our Inability to Diagnose Gross Lesions of the Appendix.*
8. Stannus, H. S. *A Case of Ovarian Cyst in a Myasaland Woman.*

1. Pasteur presents a summary of the post-operative lung complications after 3,559 laparotomies. Such complications occur with special frequency after operations above the umbilicus, are more frequent in septic cases, but are often found in clean wounds. They usually develop after the second and before the fourth day, complications arising after the first week usually being connected with septic cases. The facts presented do not support the opinion that after-effects more frequently follow ether than chloroform anesthesia. He discusses in detail a special group of cases of massive collapse of the lung.

3. Finzi discusses the radium treatment of cancer and believes that the greatest value of radium is in removing growths which are apt to become, but which at present are not, malignant. In actually malignant cases its value is limited and slight. [J. B. H.]

9. MORRELL, R. A. *The Prescription of Glasses.*
10. YELD, R. A. *The Etiology of Iritis.*

2. Oliver describes the great harm which is being done employees in trades where lead is used. He urges employees to see that existing regulations are carried out and to favor the passage of others.

4. Hall and Beattie describe a rare case of secondary syphilitic nephritis with remarks on the clinical condition and treatment. They briefly review the previously reported cases.

8. Bardswell and Chapman present an interesting paper on the temperature of the human body at rest and after muscular exertion. They prove that a rise in temperature after exercise is frequent in many normal individuals and is not, as has been often stated, a sign of pulmonary tuberculosis, even in a consumptive, nor is such a rise of temperature a definite sign of auto-inoculation. Many healthy consumptives will have a lower temperature after exercise than many normals. The paper is of interest and value. [J. B. H.]

9. THAYER, H. *Salvarsan and Hemolysis.*
10. CANNATA, S. *Pathogenesis of Hemorrhagic Purpura.*
11. MELTZER, S. J. *Murmur at the Pylorus.*

3. Michaelis has brought out the fact that the agglutination of bacteria is somewhat dependent upon the reaction of the media or solution in which they are. He has found that the point of acidity favorable for agglutination differs with different kinds of bacteria, and that, therefore, this fact may be used as a diagnostic aid in differentiating the organism present. His observations so far have been chiefly on the typhoid bacillus.

8. Kersten has found that the heart is usually small in tuberculosis whether the disease is just beginning or is far advanced. He considers, therefore, that this condition is not the result of the general wasting of the body which accompanies the disease, but is a phenomena which accompanies this disease from the start and probably plays a part in the etiology, although it is not clear just what part it plays. [C. F., JR.]

1. Pribram takes up the biological effect of urine by injection into animals. His results are more of theoretical interest than of practical value, but he seems to be opening up a new field which may eventually show practical results.

He notes in animals the effect upon the hemolysins, precipitins and complement-binding antibodies of the serum produced by the injection of urine. He finds that precipitation is much stronger in normal than albumen containing urine, while complement fixation is stronger in the albumen urine. Different parts of the urine obtained by different chemical procedures have the same effect in this regard and have been studied separately in regard to other properties. With the approach of uremia certain of these substances do not appear in the urine.

2. Bieling has found in studying the urine of patients for pepsin that the amount of this substance diminishes markedly in advanced cases of gastric cancer and not so much in other gastric conditions. He feels, however, that this sign does not appear at an early enough time for it to be of practical value from the standpoint of treatment. [C. F., JR.]

8. WELTMANN, O. *Apparent Changes in the Growth Appearances in Different Strains of Cholera Bacilli.*
9. v. TOVOLGYI, E. *A Simple Method for the Introduction of the Ephraim Endo-bronchial Spray.*

2. The author, impressed by the differing opinions of various writers in regard to the x-ray in demonstrating the size and shape of the stomach, undertook a series of experiments in which he used a solution containing differing percentages of bismuth, took his pictures at varying intervals following its use, and had his patient both lying down and standing up.

His conclusions are as follows:

(1) The less bismuth a solution contains, the more sharply is the cardiac end of the stomach defined in relation to the proportion used. The more bismuth the solution contains, the more nearly does the stomach approach a bag shape.

(2) The influence of the bismuth on the shape of the stomach is dependent solely on its weight, not on its adherence to the walls of the stomach, or its chemical reaction.

(3) The more mondamin, or other starch-containing material, the solution contains, the greater its viscosity, and the cardiac end of the stomach remains fuller, giving a reed shape to the organ.

(4) The viscosity of the solution influences the shape of the stomach far more than does the percentage of bismuth in the solution. [J. B. S., JR.]

No. 22. MAY 29, 1911.

5. The author reports three series of experiments on cats, from which he concludes that in spite of the difference between human and animal skin, one can attain results in experimental dermatology, since cutaneous reaction is dependent on the chemistry of the organism. Acidulation, as well as the addition of sodium oxalate, increases the reaction capacity of the skin, whereas increase of calcium diminishes the inflammatory exudative processes. Change in diet alters the susceptibility of the skin to external stimuli. The causes of all these phenomena might also depend on an increase of the excretion of alkalies; in diet also the varying addition of calcium might play a part. The cause of increased reaction lies in a change of the skin, which in chronic processes becomes permanent.

6. In their third and concluding paper, the authors sum up the results of their study as follows:

(*a*) Anatomic distinctions between benign and malignant forms of chorio-epithelioma are not recognized.

(*b*) Clinically also the distinction cannot be made with complete assurance.

(*c*) In differential diagnosis the clinical examination is of primary importance.

(*d*) From the anatomic structure of the tumor, the danger of its metastasis is very great.

(*e*) Treatment should be radical and should seek to avoid artificial metastasis.

(*f*) The indication for operation should be extended as far as possible. [R. M. G.]

## Obituaries.

### CHARLES GODDARD WELD, M.D. 1857–1911.

THE death of Dr. Weld is not only a deep personal sorrow to those of us who knew him intimately, but is a distinct loss to the community in which he lived. A lover and patron of art, a yachtsman who not only owned many boats, but knew how to sail them (as a man should who came from a family whose ships sailed the world over for many years with the flying horse at the topmast head), an enthusiastic and expert gunner and fisherman, a collector of things interesting and of educational value for the museums in which he was so deeply interested in Boston and Salem, a

helper to those who needed help whether strangers or friends, a thoughtful host, he will be missed by people in many professions and in all walks of life.

On the water, by the stream or in the field he was a charming companion whose first thought was always that the other fellow should have the best chance. During his trips to the woods he not only collected fish and game, but also the lame, the halt and the blind, and brought them back with him for medical advice and treatment.

There are many men in Boston who use the wealth at their command for the good of the community, but there are few whose benefactions covered a wider field or whose personal interest and care go with each gift as did his.

It was typical of him that in the last few hours of his life, when only the power of speech was left him, he spent those hours giving minute directions about the carrying on of certain works in which he had been interested and remembering his many friends.

Dr. Weld was born in Brookline, Mass., on Aug. 20, 1857. After leaving the Harvard Medical School in 1881, he was for a time in the Boston City Hospital and Chambers Street Hospital in New York. After this his active, personal medical work was given up on account of the larger financial responsibilities that he was obliged to assume, but he never lost his interest in things medical. Perhaps the Boston Dispensary was the institution to which he gave the most time and thought, though other medical charities were bountifully aided. One can speak only of those with which one is personally connected, for he was a man who never spoke of his gifts; but it is safe to say that there is hardly a medical charity in Boston that he has not aided, as well as many elsewhere. His interest in the Massachusetts General Hospital was always active, the Gay ward and the skin and throat ward, called much against his will the Weld ward, he built, and the surgical instruments were by him constantly replenished and kept up to the highest possible standard. Should new instruments, however expensive, be needed, the chairman of the instrument committee had only to order them, approve the bill and it was paid. The same was true of the x-ray outfit, which was largely his gift.

One day it was suggested that a wonderful collection of Peruvian skulls was in the country and for sale. He was told that the curator of the medical school wished to secure this, the most remarkable collection in the world, showing prehistoric trephining, and the next day they were the property of the school, the only condition of the gift being that no one should know who gave them.

One of the things that greatly interested him in the last year of his life was the building and equipping of a private hospital where, though not an active surgeon himself, he spent many hours of his time. The new Cancer Research Hospital was another institution in which he took a great interest. No deserving person ever needed medical aid that he was not ready to help to give him that aid, friend, acquaintance or stranger, it only mattered that they were in need.

His list was a long one and no one person knows all the items on it. No one knows, for instance, to how many men he has given an education at some college, the Institute of Technology or the Medical School, but they are not a few.

In his giving he was discriminating and careful as well as generous, and he was as willing to fight what he thought was wrong as to give to that which was deserving.

The medical profession of Boston has lost a true friend, a wise and able advisor and a generous benefactor.

## ALEXANDER BRUCE, M.A, M.D., LL.D., F.R.C.P.E.

Dr. Alexander Bruce, who died on June 4, at Edinburgh, was born in Ardiffery, Cruden, Aberdeenshire, Scotland, in 1854. He graduated from the University of Aberdeen in 1874 with highest classical honors, and began the study of medicine at the University of Edinburgh. He studied also at Vienna, Heidelberg, Frankfort and Paris; and returning to Edinburgh, became a Fellow of the Royal College of Physicians in 1879, subsequently receiving a gold medal for his thesis for the degree of M.D.

After serving for a time as assistant clinical clerk, at the West Riding Asylum in Yorkshire, England, he settled in the practice of medicine at Edinburgh, devoting himself especially to neurology, in which he acquired international eminence. He had served as lecturer on pathology at the Surgeons' Hall, as pathologist to the Royal Infirmary, to the Royal Hospital for Sick Children, and to the Longmore Hospital for Incurables; and at the time of his death held the appointment of physician and lecturer on clinical medicine in the Royal Infirmary. He had also been Morrison Lecturer on mental diseases at the Royal College of Physicians. He founded and edited the *Review of Neurology and Psychiatry* and is known as the author of several important works, notably "Illustrations of Mid- and Hind-Brain," and "The Topographical Atlas of the Spinal Cord," besides having been a frequent contributor to medical journals and to the *Transactions* of the Royal Society of Edinburgh, of which he was a member. He had also published a translation of Thoma's "Manual of Pathology," and at the time of his death had just completed a translation of Oppenheim's "Textbook of Nervous Diseases."

In 1898 Dr. Bruce was made a corresponding member of the Neurological Society of Paris. In 1908 he was awarded the Keith Prize for his paper entitled "Distribution of the Cells in the Intermediolateral Tract of the Spinal Cord." And in 1909, he received the honorary degree of LL.D. from the University of Aberdeen.

Dr. Bruce was an able and original thinker and a hard worker, and his death is a great loss to medical science. Of upright character and singu-

lar charm of manner, he was beloved by his patients and by all who knew him. He is survived by his widow, by two daughters and by three sons, one of the latter being also a physician.

JOHN QUINCY ADAMS McCOLLESTER, M.D.

DR. JOHN QUINCY ADAMS MCCOLLESTER, who died on June 23, at Waltham, Mass., was born in Marlboro, N. H., on May 3, 1831. After graduating from the University of Norwich, Vt., in 1853, he entered the Jefferson Medical College, Philadelphia, from which he received the degree of M.D. in 1856. He taught for a time in the Dartmouth Medical School, and then began the practise of his profession at South Deerfield, Mass., but subsequently removed to Groton Junction, now Ayer, Mass. In 1862 he was commissioned surgeon of the Fifty-Third Massachusetts Regiment, and served with that command throughout the remainder of the Civil War. He then settled in Groton, Mass., but later removed to Harvard, Mass., and in 1887 to Waltham. He had served for some years as medical examiner and secretary of the United States Civil War Veterans' Pension Board. He retired in 1903. He was a Fellow of The Massachusetts Medical Society, a member of the Boston Medical Library Association and of the Waltham Medical Club, a vice-president of the General Alumni Association of Jefferson Medical College, and a former president of the New England Association of Jefferson Medical College Alumni. He is survived by two daughters and two sons.

EDWIN PEABODY GERRY, M.D.

DR. EDWIN PEABODY GERRY, of Jamaica Plain, who died on June 21, at Phillipston, Mass., was born in Standish, Me., on Nov. 2, 1846. He fitted for college at the Boston Latin School, received the degree of A.B. from Dartmouth in 1869, and in 1874 that of M.D. from the Harvard Medical School. After serving as house-officer at the Boston City Hospital, he began the practise of medicine in Jamaica Plain. He took an active interest in local affairs, and had served in the Boston city government as alderman from his district. He was a Fellow of The Massachusetts Medical Society, a member and former president of the Norfolk District Medical Society, a former vice-president of the Boston City Hospital Alumni Association, a member of the West Roxbury Medical Club, of the Clinical Club and of the Harvard Medical Alumni Association. He is survived by his widow.

## Miscellany.

### HARVARD SUMMER SCHOOL OF MEDICINE SERIES OF LECTURES.

ON Friday, June 29, will be given the first of a series of general lectures announced by the Harvard Summer School of Medicine. This is the third season during which such a course has been offered. The lectures, which are open free to all members of the medical profession and of the Summer School of Medicine, will be held at 5 P.M., in Room 201 of the Administration Building of the Harvard Medical School. The complete schedule is as follows:

1. *Friday, June 30.* J. G. Mumford, M.D., Instructor in Surgery. Aspects of Abdominal Ptosis. (Illustrated by Lantern Slides.)

2. *Friday, July 7.* R. W. Lovett, M.D., Assistant Professor of Orthopedic Surgery. Surgical Aspects of Poliomyelitis.

3. *Tuesday, July 11.* H. A. Christian, M.D., Hersey Professor of the Theory and Practice of Physic. Uncinariasis.

4. *Friday, July 14.* P. C. Knapp, M.D., Clinical Instructor in Diseases of the Nervous System. Hemiplegia.

5. *Tuesday, July 18.* C. L. Scudder, M.D., Lecturer on Surgery. Stenosis of the Pylorus in Infancy. (Illustrated by Lantern Slides.)

6. *Friday, July 21.* E. C. Briggs, M.D., D.M.D., Professor of Dental Materia Medica and Therapeutics. Interstitial Gingivitis.

7. *Tuesday, July 25.* Hugh Cabot, M.D., Instructor in Genito-Urinary Surgery. Selected Topic in Renal Surgery.

8. *Friday, July 28.* C. M. Smith, M.D., Assistant in Syphilis. Modern Methods in the Treatment of Syphilis.

9. *Tuesday, August 1.* Oscar Richardson, M.D., Assistant Pathologist, Massachusetts General Hospital. Diseases of the Kidney, a Practical Classification from the Clinico-Pathological Standpoint.

10. *Friday, August 4.* J. L. Morse, M.D., Assistant Professor of Pediatrics. Medical Aspects of Poliomyelitis.

11. *Tuesday, August 8.* C. M. Green, M.D., Professor of Obstetrics. Cæsarean Section.

12. *Friday, August 11.* J. S. Stone, M.D., Assistant in Surgery. Certain Aspects of Surgery in Children.

13. *Tuesday, August 15.* E. A. Locke, M.D., Instructor in Clinical Medicine. Public Aspects of the Tuberculosis Problem.

14. *Friday, August 18.* W. J. Dodd, M.D., Instructor in the Use of the Roentgen Ray. Therapeutic Uses of the X-Ray.

15. *Tuesday, August 22.* E. P. Joslin, M.D., Instructor in the Theory and Practice of Physic. The Treatment of Diabetes Mellitus.

16. *Friday, August 25.* David Cheever, M.D., Demonstrator of Anatomy. The Lymphatic System and its Relation to Surgical Conditions.

17. *Tuesday, August 29.* G. B. Magrath, M.D., Instructor in Legal Medicine. The Massachusetts System of Medico-legal Inquiry.

### PREVALENCE AND PREVENTION OF RABIES IN THE UNITED STATES.

A BULLETIN (No. 449) has recently been issued by the United States Department of Agriculture relative to the increase of rabies in this country and informing farmers of the measures necessary for its control and eradication. This disease,

Welch Medical Lib. 15150

which has a mortality of 100% in untreated cases, is transmitted by the bite of various small animals, chiefly of the dog. The bulletin recommends the muzzling of all dogs as the surest and quickest means of preventing its spread. Since this measure has been adopted in European countries the disease there has practically disappeared.

In 1897 rabies was known to exist in only four of the United States. In 1908 it occurred in 18 out of the 20 states from which reports were received, and Dr. John R. Mohler, chief of the pathologic division of the bureau of animal industry and author of the bulletin, expresses his belief that it exists in every state except possibly Idaho, Utah, Nevada and Oregon. It is said to be most prevalent in Texas.

There are now in the United States 20 Pasteur Institutes for the treatment of rabies in man, and several hundred persons are treated by them annually, in 1908 nearly 1,500. The expense, suffering and apprehension involved might all be prevented and the disease eradicated by universal muzzling of dogs. "The islands of Australia, Tasmania, New Zealand, St. Helena, and the Azores have never become infected with rabies," and rigid quarantine measures are employed to keep the disease out. Effective sanitary regulation awaits only its opportunity to eliminate the infection from the United States, but this it cannot obtain without the development of a general demand for it by public opinion.

## RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, JUNE 17, 1911

| CITIES. | Reported deaths in each. | Deaths under five years. | CITIES. | Reported deaths in each. | Deaths under five years. |
|---|---|---|---|---|---|
| New York | 1,232 | 358 | Waltham | 7 | — |
| Chicago | 544 | 156 | Brookline | 3 | — |
| Philadelphia | — | — | Chicopee | 8 | 4 |
| St. Louis | — | — | Gloucester | 4 | — |
| Baltimore | — | — | Medford | 6 | — |

## APPOINTMENTS.

THE BOARD of Scientific Directors of the Rockefeller Institute for Medical Research announce the following appointments to the staff of the Institute: Alfred F. Cohn, M.D., Associate in Medicine; Arthur W. M. Ellis, N.B., Assistant Resident Physician; Alphonso R. Dochez, M.D., Assistant Resident Physician; Frank V. Bancroft, Ph.D., Associate in Experimental Biology; Reinhard H. Beutner, Eng. D., Assistant in Experimental Biology; James B. Murphy, M.D., Assistant in Pathology; J. J. Bronfenbrenner, Fellow in Pathology; Frederick B. La Forge, Ph.D., Assistant in Chemistry; Henry K. Marks, M.D., Assistant in Pathology; Helen L. Fales, Research Scholar in Chemistry; Angelia M. Courtney, Assistant in Chemistry.

## RECENT DEATHS.

DR. JOHN FRANKLIN WHITMYER, chief medical inspector in the New York City Health Department, died from cardiac disease on June 23, at the age of forty-seven years. He was born in Schenectady, N. Y., and was graduated from the College of Physicians and Surgeons, New York, in 1890. He had been in the service of the Health Department nearly twenty years, and four years ago he succeeded Dr. Alonzo Blauvelt, resigned, as chief inspector of contagious diseases.

DR. CARL H. LELLMANN, a prominent German physician of New York, died on June 21 in Karlsruhe, Germany, at an advanced age. He was graduated from the University of Göttingen in 1854. Dr. Lellmann retired from practice a year or two ago, and at that time he was consulting physician to the German and St. Francis Hospitals.

DR. WILLIAM HENRY MORSE, JR., an instructor in the New York College of Dentistry, died on June 17, from Bright's disease. He was a son of Dr. William H. Morse of New York, and was twenty-nine years of age.

DR. WILLIAM P. BRIERLY, of Albany, N. Y., was instantly killed on June 22, while attempting to board a trolley car. He was a graduate of the Albany Medical College in 1886.

DR. DANIEL B. NUGENT, of Henderson, N. Y., the oldest physician in Jefferson County, died on June 20, from injuries received by being struck by a bicycle. He was ninety-two years of age.

DR. JOHN JEREMIAH VAN RENSSELAER, a retired physician of Swartswood, Essex County, N. J., died on June 18, at the age of seventy-five years.

DR. GEORGE WASHINGTON BAILEY, who died on June 21, at Elizabeth, N. J., was born in Gloucester County, N. J., on Dec. 5, 1840. At the outbreak of the Civil War, he enlisted in the Twenty-Fourth New Jersey Volunteer Regiment, and served in the ranks of that command throughout the war. In 1868 he obtained the degree of M.D. from the University of Pennsylvania, and for a few years practised his profession, but retired on account of ill-health in 1872, and since that time had been largely concerned in the real estate and coal business. He was a trustee of the Presbyterian Hospital of Philadelphia, and was interested in numerous other charitable, benevolent, and philanthropic institutions and enterprises.

DR. ISAAC W. BLACKBURN, chief pathologist at the Government Hospital for the Insane, at Washington, D. C., died of chronic entero-colitis in that city last week, at the age of fifty-nine years. He had formerly been professor of pathology at George Washington and Georgetown Medical Schools. He is survived by his widow.

DR. MONDANA FULLER DE HART, who died last week at Freedom, N. J., was a native of New England. She received her professional degree from the Woman's Medical College in New York. She settled in 1865 at Jersey City, N. J., and was the first woman to practise medicine there. She retired two years ago. She is survived by her husband, by three daughters, and by one son. Two of her daughters were physicians.

EDWIN PEABODY GERRY, M.D., M.M.S.S., died at Phillipston, Mass., on June 22, 1911, aged sixty-four years.

JOHN QUINCY ADAMS MCCOLLESTER, M.D., M.M.S.S., died at Waltham, Mass., on June 23, 1911, aged eighty years.

## BOOKS AND PAMPHLETS RECEIVED.

Spirochaetes. By W. Cecil Bosanquet, M.A., M.D. W. B. Saunders Co.

Structure and Functions of the Body. By Annette Fiske, A.M. W. B. Saunders Co.

Golden Rules of Pediatrics. By John Zahorsky. C. V. Mosby, St. Louis, Mo.

Education. How Old and New. By James J. Walsh, M.D., Ph.D. Fordham University Press. 1910.
